is currently used mainly in metalworking operations such as processing of ores, the production of batteries, power, thermal, and nuclear power generation, and some industrial wastewater treatment systems (Koltuniewicz and Drioli 2008; Koltuniewicz 2010). General examples of applications of biosorption are (I) removal of harmful substances from the environment and (II) separation of valuable substances from multicomponent mixtures. In the first case, the desired feature and the main value of biosorption are its low cost and widespread availability of biosorbents. Dealing with large amounts of contaminated water, which must be processed and, moreover, contains rather diluted substances to remove, such as heavy metals, organic substances or radioactive materials, is the biggest challenge for process engineering. In these cases, almost all methods of separation fail because their costs are rising dramatically. Therefore, the use of cheap biosorbents, which are often waste materials (algae, fungi, bacteria, sawdust, bark, etc.), may be helpful, especially for environmental protection.

In the second case (II), selective and specific sorbents with a high affinity for precious substances are sought. This method can also be useful to concentrate the atoms of noble metals such as gold, platinum and uranium, from industrial waste water, or even diluted in sea water.

In both cases, the use of membrane-assisted biosorption, namely, the “membrane biosorption,” may be recommended (Koltuniewicz and Bezak 2002). The membranes allow for easy concentration of finely ground biosorbents (Fig. 1) or cells (Fig. 2), which is impossible in the thick layer of packed columns. Very fine grinding is desirable because of the possibility of increasing the surface of sorption and shortening of the diffusion paths to active sites. This increases the efficiency of sorption, even in dilute suspensions. However, the costs of milling and additional operations such as drying, sorting, etc. should always be taken into account. So in order to make real use of biosorption, the calculations must be performed in any case. The next part shows the equations needed to calculate the membrane biosorption process.

Tubular ceramic (Membralox® 19 tubes)	0.0020	0.80
Capillary (Romicon®, d = 1 mm)	0.0035	0.66

Calculations of Membrane Biosorption Process

The obvious drawback of membrane biosorption is the quick saturation of the thin layer of biosorbent on membrane surface is rapidly progressing with time, until equilibrium is reached. The equations describing the equilibrium and kinetics for biosorption process can be determined on the basis of experimental data (see Tables 1, 2, 3, and 4 in Fig. 1).

The concentration in the biosorbent (q) varies with time, due to its saturation with solute (i.e., xenobiotic), which can be expressed in the formula:

$$q(t) = q^* - (q_0 - q^*) \cdot e^{-kt}$$

Where:

- $q(t)$ [kg_{solute}/kg_{biosorbent}] – solute (xenobiotic) concentration in the biosorbent
- q^* – equilibrium value of solute concentration in the biosorbent (maximum uptake see Table 1)
- q_0 – initial solute concentration in the biosorbent, e.g., solute concentration in the sorbent which is supplied with the feed

During dead-end mode of operation, when the unaffected biosorbent lies on the membrane surface, and the liquid passes through its layer, the concentration in the fluid changes according to equilibrium. Change of concentration over time in the permeate stream can be then calculated from the mass balance (see Fig. 3) (Koltuniewicz and Bezak 2002; Koltuniewicz and Witek 2004). The balance of xenobiotic in an open system, during the flow of fluid through a layer of biosorbent, permeates flow results in a superposition of two effects: (1) the tendency to reduce the concentration of xenobiotic in the permeate due to its biosorption and (2) the tendency to increase the concentration as a result of inflow of xenobiotic, with the liquid. Thus, the relationship has a minimum of the xenobiotic concentration in the permeate after biosorption:

$$C_P(t) = C_R - \frac{k \cdot X_m \cdot \delta \cdot (q^* - q_R)}{J - k \cdot \delta} \cdot \left[e^{-kt} - e^{-\frac{J}{\delta}t} \right]$$

Where:

- $C_P(t)$ – instantaneous concentration of solute in the permeate
- C_R [kg_{solute}/m³_{retentate}] – constant concentration of solute in the retentate inflow,
- X_m [kg_{biomass}/m³_{retentate}] – average biomass concentration on the membrane surface

Membrane Biosorption, Fig. 3 Purity of permeate after the process of membrane biosorption in dead-end and cross-flow modes of operation

δ [m] – thickness of the sorbent layer on the membrane

k [s^{-1}] – biosorption kinetic constant

q_R [$kg_{\text{solute}}/kg_{\text{biomass}}$] – solute concentration in the sorbent in the retentate

q^* – maximum uptake, i.e., equilibrium value of the solute concentration in the sorbent

J [m^3/m^2s] – permeate flux

t [s] – real time of the process

It should be underlined that sorption process in dead-end mode is unpractical because of very small volume of active biosorbent layer at the membrane surface. Therefore, to maintain stationary conditions of the process, some way to remove the thin active layer of sorbent from the membrane surface after appropriate process time must be found. Duration, after which the concentration of solute in the permeate is the minimum, may be selected as a time of the periodic back flushing and can be calculated from the formula:

$$t(C_P^{\min}) = \frac{\ln\left(\frac{k\delta}{J}\right)}{k - \frac{J}{\delta}}$$

Methods to reduce the concentration polarization layer are well known in the membrane processes to maximize the permeate flux. They are turbulences or shear forces, shear-induced diffusion, lifting forces, pinch effects, lateral migrations, scouring effects, gas sparging, etc. We can now apply them for controlled renewal of a biosorbent film from the surface of the membrane by using hydrodynamic effects during cross flow. Application of Danckwerts model allows to determine the optimal rate of surface renewal (Koltuniewicz and Witek 2004).

$$s_{opt} = \sqrt{\frac{k \cdot J}{\delta}} \text{ for } C_P^{\min} \text{ when } \frac{dC_P^m}{ds} = 0$$

The optimal conditions for renewing the surface we get when the lowest concentration of the xenobiotic in the permeate (i.e., the highest possible purity) of cross-flow conditions can be achieved. This is when the frequency of renewal of the sorbent film(s) is synchronized with the (i) flow of permeate “ J ,” (ii) thickness of the sorbent layer on the membrane “ d ,” and (iii) the kinetics of sorption “ k ” (see Fig. 1). Then the average concentration in the permeate outflow from the entire

surface of the membrane (i.e., the sum of the concentrations in the streams flowing from all of

its components) can be expressed by the formula (see also Fig. 3 at continuous line):

$$C_P^m = C_R - \left[\frac{1 - e^{-(k+s) \cdot t_p}}{k + s} - \frac{1 - e^{-\left(\frac{J}{\delta} + s\right) \cdot t_p}}{\frac{J}{\delta} + s} \right] \cdot \frac{k \cdot X_m \cdot \delta \cdot (q^* - q_R)}{J - k \cdot \delta} \cdot \frac{s}{1 - e^{-s \cdot t_p}}$$

After the long duration of process, this concentration becomes constant, leveling off on the asymptotic value independent on time of the process t_p (see Fig. 1 dashed line).

$$C_P^m = C_R - X_m \cdot (q^* - q_R) \cdot \frac{k \cdot \delta \cdot s}{(J + s \cdot \delta) \cdot (k + s)}$$

The rate of the surface renewal depends on many hydrodynamic parameters and must be determined experimentally. However, rough estimates assuming close to the water systems can use a simple exponential dependence on average velocity retentate at different membrane modules, which were presented in Koltuniewicz (1992).

$$s = m \cdot u^n$$

All the above data and formulas can be very helpful in practical use of opportunities and potential of membrane biosorption as a new separation process.

Introduction

Membrane biotechnology is the integration of membrane separation with biotechnology and has been widely used in various biotechnology processes, e.g., reaction, separation, clarification, and recovery. Membrane separation is very suitable for biological processes since it is usually operated at mild temperatures and pressures and requires no phase changes or chemical additives, thereby minimizing the extent of denaturation, deactivation, and/or degradation of biological products (Charcosset 2006). The sterile filtration of fermentation media, purification buffers, and protein product pools is a standard practice in

industry, and high-resolution applications of membrane separation in biotechnology processes for improved protein-virus separation, protein purification by high-performance tangential-flow filtration, and enhanced membrane chromatography are also targeted (van Reis and Zydney 2001).

Membrane biotechnology includes membrane separation process, membrane bioreactor, membrane chromatography, membrane contactor, and other combined processes. Membrane separation processes are utilized to recover macromolecules and retain suspended solids and solutes of large molecular weight. Typical membrane separation processes are microfiltration, ultrafiltration, nanofiltration, and reverse osmosis filtration. Novel separation processes, e.g., forward osmosis and membrane distillation, have been also developed. Applications of membrane separation include sterile filtration (bacterial removal), clarification of fermentation broths, product concentration and recovery, antibiotic production, biorefineries, renewable fuel production, and so on (Charcosset 2006; Huang et al. 2008; Addehagh et al. 2014).

Membrane bioreactors (MBRs) combine activated sludge processes with advanced membrane separation. Current available commercial MBR processes employ the membrane ostensibly as a filter, rejecting the solid materials or solutes with large molecular weight developed by the biological process to provide a clarified and disinfected product (Judd 2011). MBR types are generally divided into several categories based on the purpose of membrane usage: biomass separation membrane bioreactor (BSMBR), membrane aeration bioreactor (MABR), extractive membrane bioreactor (EMBR), and ion-exchange membrane bioreactor (IEMBR) (Stephenson et al. 2000; Gu and He 2002; Oehmen et al. 2006). BSMBR, usually termed as MBR (see the related term, MBR), is the most prevalent among the different types (Wang et al. 2008).

Membrane chromatography is used as an alternative to conventional resin-based chromatography columns, for a large range of chromatographic purification schemes, including ion-exchange, hydrophobic, reversed-phase, and affinity chromatography. Membrane materials for chromatographic applications include cellulose, polysulfone, polyamide, hydrazide, and composite

membrane such as blend of polyethersulfone and polyethylene oxide coated on all surfaces with a covalently bound layer of hydroxyethylcellulose (Charcosset 1998). Commercial membranes include flat sheet systems (Pall, New York), membrane stacks (Sartorius, Göttingen, Germany), radial-flow cartridges (CUNO Europe, Cergy-Pontoise, France), and hollow-fiber modules (Kinetic Systems Inc., St. Louis, MO) (Charcosset 2006).

Membrane contactor can be defined as the connection of two phases A and B through membrane pores. Membrane distillation involves a temperature gradient to promote water vapor to permeate through a porous hydrophobic membrane. Membrane emulsification involves using a pressure to force the dispersed phase A to permeate through a membrane into the continuous phase B, which flows tangentially to the membrane surface. Membrane pores act as parallel capillaries for the introduction of phase A into phase B. Membrane contactors are applied for the preparation of emulsions (membrane emulsification) and for the preparation of crystals (membrane crystallization).

Membrane separation can be also integrated into other novel processes. For example, membrane separation has been used in microbial fuel cells (MFCs), which use bacteria as the catalysts to oxidize organic and inorganic matter and generate current. In a typical MFC, a cation-exchange membrane (CEM) is applied to separate the anode and cathode compartments, through which protons in the system can migrate (Logan et al. 2006).

The membrane properties could be further enhanced by the modification of its physicochemical characteristics (e.g., porosity, hydrophilicity, zeta potential, and pore size) to improve the efficiency in reaction, separation, clarification, and recovery schemes (Wang et al. 2013). The rapid development in membrane technology will allow membranes to play an important role in the evolution of the next generation of biotechnology processes.

Membrane Capacitive Deionization

Maarten Biesheuvel

Wetsus, European Centre of Excellence for Sustainable Water Technology, Leeuwarden, The Netherlands

Membrane capacitive deionization, MCDI, is a technology for water desalination based on the use of an assembly of a spacer channel, two ion exchange membranes, and two porous carbon

electrodes. Of the two electrodes, one is the cathode, in which cations are adsorbed during desalination, and the other is the anode. In front of the cathode, a cation exchange membrane is placed, while an anion exchange membrane is placed in front of the anode. MCDI is a cyclic process, in which for some time freshwater is produced, followed by a period in which a concentrate stream leaves the device. To increase water recovery, the second period (ion release) must be short relative to the first period (ion adsorption).

In MCDI, upon transferring electrical charge from cathode to anode, against a cell voltage difference opposing this electrical charge transfer, the ions are removed from the water flowing through the spacer channel and are adsorbed in their counter electrode. In this way water is obtained which is desalinated to a certain degree. After some time, the electrodes have reached their adsorption capacity, and the electrical current is reversed, thereby releasing the ions from the electrodes, leading to a stream of brine (concentrate) flowing from the device.

As each layer in the assembly is about 100–300 μm of thickness, a complete cell, including also “graphoil” current collectors on either side, is about 1.0–2.0 mm of total thickness. Thus, in a “stack” of 10 cm of height, it is possible to pack up to 100 of such cells. The current collectors serve to inject the electrical current from the external circuit into the porous electrodes, which are accessible for the water and the ions. Ion storage is based on the formation of electrostatic double layers within the nanopores in the carbon electrode particles, where electrical charge is locally charged compensated by counterions.

The advantage of MCDI over the related technology without membranes, CDI, is that during the charging or desalination step, co-ions (ions of the same charge sign as the electrode) are blocked from leaving the electrode region. This effect does occur in CDI and limits the charge efficiency, i.e., the amount of salt molecules removed from the water per amount of charge transferred. A second advantage of MCDI is that upon reversing the voltage during cell discharge, it is possible in MCDI to completely remove all counterions from their electrode, thereby increasing the desalination capacity in a next cycle.

Membrane Charge

Paul Melvyn Williams
College of Engineering, Swansea University,
Swansea, UK

Membrane charge: Membranes acquire a characteristic electric surface charge when contacted with an aqueous solution. For both organic and inorganic membranes, the surface of a membrane can become charged due to the dissociation of specific ionizable groups on the surface. These ionization reactions depend on the pH and the electrolyte in the bulk solution in contact with the membrane. The charge and resulting potential of the membrane depend strongly on the pH of the system because the majority of the membrane functional groups protonate and deprotonate over the pH range.

As a direct result of the fabrication materials traditionally employed in membrane manufacture, most membranes are either neutral or negatively charged in an aqueous processing environment (Tsuru et al. 1998; Childress and Elimelech 1996). However, positively charged membranes can be produced by surface modification of the membrane (Cheng et al. 2011). The most common technique for evaluating the membrane surface charge (zeta potential) is via streaming potential measurements (Hunter 1981).

The charge of the membrane is significant to membrane performance because charge affects the electrostatic repulsion between the ions or charged molecules and the membrane surface. This can also have an impact on membrane fouling as well.

Membrane Charge (Zeta Potential) Effect

Paul Melvyn Williams
College of Engineering, Swansea University,
Swansea, UK

Membrane surface charge (zeta potential) effect: The membrane surface charge or zeta potential is most often characterized using the streaming potential method (Hunter 1981) (see “► [Membrane Charge Characterization](#)”). The charge of a membrane is significant to membrane performance because charge affects the electrostatic repulsion between the ions or charged molecules and the membrane surface.

Due to the materials used in the fabrication of membranes, most membrane surfaces show a negative charge at neutral pH values (i.e., pH 7). However, due to the amphoteric nature of the chemical groups on the surface of a membrane, the charge may be altered by adjusting the solution conditions (i.e., pH and electrolyte concentration) (Cheng et al. 2011). Surface modifications may also be made to membranes in order to change the charge from negative to positive (Cheng et al. 2011; Kobayashi et al. 1996).

Membrane surface charge has a big influence on the rejection of charged species (i.e., salt, charged dyes, amino acids, etc.) for nanofiltration membranes. The isoelectric point (Hunter 1981)

(the pH at which point where there is no effective charge) of a membrane can be determined from the minimum rejection value obtained when filtering a charged species (like sodium chloride (NaCl)), by varying the pH value at a fixed electrolyte concentration and constant applied pressure (Cheng et al. 2011).

For ultrafiltration membranes, the charge on the membrane surface will affect the interactions between the membrane and the particles in the feed solution. If the charge on both the membrane surface and the particles is of the same sign, repulsion will occur, and there will be less fouling and concentration polarization at the membrane surface. However, if the charge on the membrane surface is of the opposite sign to the particles, attractive forces will dominate and the membrane will foul easily, thus reducing performance. The membrane charge can have a significant effect on the flux obtained (Bacchin et al. 2006).

The determination of the membrane surface zeta potential can also be used as an indicator for membrane fouling (Lawrence et al. 2006; Al-Amoudi et al. 2007). The effect of foulants can be investigated, and based on the measurement results, the membrane surface can be specifically treated to decrease membrane fouling and extend the membrane lifetime (Lawrence et al. 2006; Al-Amoudi et al. 2007).

Membrane Charge Characterization

Paul Melvyn Williams

College of Engineering, Swansea University,
Swansea, UK

The surface charge density and thus membrane charge of a porous membrane are related to the zeta potential of the membrane. There are several procedures that allow characterization of the membrane zeta potential and thus surface charge.

Streaming Potential

When an electrolyte solution flows across or through a stationary, charged membrane, the flow of liquid tangential to the material drags the excess charges near to the material wall downstream. This causes the build-up of an electric field which drives a current in the reverse direction. The streaming potential that is induced may be measured using electrodes. The zeta potential is calculated from the measured streaming potential using the Helmholtz-Smoluchowski equation (Smoluchowski 1905; Abramson 1934) with the Fairbrother and Mastin substitution (Fairbrother and Mastin 1924). The streaming potential may be measured either across the surface of the membrane, by forming a thin channel and pumping the electrolyte through this channel, or through the pores enabling measurement of the streaming potential across the membrane (Nystrom et al. 1994).

Electroosmosis

A simple “dipped cell” apparatus can be used for measuring the electroosmotic flow rate across a microporous membrane (Bowen and Clark 1984).

The membrane is held at the end of a deep tube immersed in the thermostated electrolyte. Two electrodes are used. The first one is positioned behind the membrane and the second one is positioned outside the tube. At the beginning of the experiment, the liquid level both inside and outside the tube are the same. A constant current is then applied between the two electrodes which induces an electroosmotic flow of electrolyte in the tube. Overflowed electrolyte is transferred to an electronic balance. Zeta potential was determined by measuring the rate of electroosmosis across the membrane.

The literature shows that the streaming potential method has been much more widely studied in comparison to electroosmosis phenomena.

For nanofiltration membranes, it is also possible to evaluate the effective membrane charge density, X_d , by fitting experimental data of the variation of electrolyte rejection with concentration (Bowen et al. 1997). However, this parameter is essentially a fitting parameter and has no real physical basis.

Membrane Classification

► Membrane (Definition, Function, Structure)

Membrane Collapsing

Alexey Volkov

A.V. Topchiev Institute of Petrochemical Synthesis Russian Academy of Sciences (TIPS RAS), Moscow, Russia

Membrane collapsing is irreversible changing in the membrane structure (porous structure) as a result of external factors. Membrane collapsing is mostly typical for the membranes with a porous structure that artificially forms during the membrane casting (e.g., by phase inversion). Membrane collapsing can take place mainly in two following cases: (i) drying or non-proper replacement of solvent/non-solvent contained in the membrane and (ii) high transmembrane pressure that exceeds mechanical stability of used membrane material. The former one is mostly typical for NF or RO membranes. To preserve a fine (porous) structure of selective layer, RO/NF membranes are commonly impregnated by non-volatile solvent like glycerin or supplied in a wet state (in preserve solution) (Mallevalle and Odendaal 1996). Once the membrane is dried, the membrane cannot retrieve its initial filtration characteristics due to dramatic irreversible changes within the structure of selective layer. Therefore, the membranes are installed in a wet state and then preserve agent is washed out during filtration of pure water (membrane pretreatment). If the membrane should be operated in nonaqueous media, it is recommended to replace the preserve solution by a number of solvents or its mixtures in order to provide step-wise change of solvent surface tension. Non-proper solvent exchange could lead to noticeable deviation in membrane performance (Volkov et al. 2008).

Since the porous structure of the selective or support layers could have a limited mechanical stability, the membrane manufacturers usually provide the information about the maximum transmembrane pressure at which the membrane still exhibits the claimed characteristics. It should

Membrane Collapsing, Fig. 1 Collapsing of membrane porous structure: initial membrane (*left*), collapsed membrane after TMP of 20 bar (*right*)

be mentioned that increase of polymer segments mobility (e.g., transition from glassy to rubbery state) or membrane swelling (polymer plasticization) may also lead to membrane collapsing; it is commonly observed for high-pressure gas separation or organic solvent nanofiltration (Nunes and Peinemann 2006). Figure 1 illustrates typical example of collapsing of membrane porous structure as a result of applying of high transmembrane pressure that exceeds the mechanical stability of the support layer.

In a case of the polymer with intrinsic microporosity, the change in porous structure is referred as partial relaxation of free-volume structure also called as a physical aging. Membrane can be also collapsed as a whole construction if high pressure is applied on shell side (outside) of hollow fiber membrane.

Membrane Compaction

Alexey Volkov

A.V. Topchiev Institute of Petrochemical Synthesis Russian Academy of Sciences (TIPS RAS), Moscow, Russia

Membrane compaction can be considered as a compression of the membrane under applied pressure resulting in decline of transport characteristics of the membrane. Membrane compaction is quite commonly observed phenomena, especially decrease of initial membrane transport parameters in pressure driving processes like gas separation or membrane filtration. Typically, increase pressure drop across the membrane leads to more pronounced effect of membrane compaction. If the membrane is already compacted at the operated pressure, steady-state performance can be expected. However, the flux decline over the time can be also attributed to membrane fouling, which is known as a partial blockage of membrane surface and/or pores inside of the membrane by components of the feed. Unfortunately, it is difficult to distinguish the effect of membrane compaction from membrane fouling, especially, during the operation with multicomponent mixtures.

Membrane Compaction,

Fig. 1 Effect of reversible membrane compaction on the ethanol permeability through dense membrane of PTMSP: three filtration series in which the transmembrane pressure was reduced from 200 (■), 150 (●), or 100 bar (▲), respectively (Grekhov et al. 2012)

For minimization of the time required for preliminary membrane compaction, it is recommended to start experiment with the highest pressure and then stepwise decrease the transmembrane pressure. Membrane compaction cannot be avoided, but its effect on membrane performance can be controlled; moreover, the initial membrane compaction has a greater impact on the membrane. From this end, the membrane manufactures quite often provide the protocol of preliminary membrane conditioning that has to be followed in order to guarantee claimed membrane characteristics.

Membrane compaction as a physical compression can have reversible, partially reversible or irreversible effect on membrane structure. The membrane collapsing is one of the examples of irreversible membrane compaction, and this effect is attributed to mechanical destruction of porous structure of the membrane as a result of applied pressure. Increase of polymer segment mobility (e.g., transition from glassy to rubbery state) or membrane swelling (polymer plasticization) may also lead to more pronounced effect of membrane compaction under applied pressure; it is commonly observed for high-pressure gas separation or organic solvent nanofiltration (Nunes and Peinemann 2006). Figure 1 illustrates an example of reversible membrane compaction, when the membrane is recovering its transport properties

with a decrease of the transmembrane pressure; as can be seen, the normalized liquid permeability is a function of pressure here.

The selective recovery of evaporated wastewater from industrial gases can be carried out through membrane condensers.

Membrane Condenser,

Fig. 1 Scheme of the membrane condenser process for the recovery of evaporated “waste” water from flue gas as feed

The principle of working of this new membrane technology has been recently introduced by Macedonio et al. 2013 and consists in condensing and recovering the water contained in a saturated gas on the retentate side of a membrane module, by exploiting the hydrophobic nature of the membrane, whereas the dehydrated gases pass through the membrane in the permeate side.

Figure 1 schematizes the membrane condenser principle.

The gaseous stream (e.g., flue gas) exiting from the power plant, cooling towers, stacks, etc. at a certain temperature and relative humidity is fed to the membrane condenser kept at a lower temperature for cooling the gas up to a supersaturation state. The water condenses in the membrane module once this stream is brought into contact with the retentate side of the microporous membranes; the hydrophobic nature of the latter prevents the penetration of the liquid into the pores letting pass the dehydrated gases through. Therefore, the liquid water is recovered at the retentate side, whereas the other gases at the permeate side of the membrane unit. In comparison with the traditional technologies, the membrane condenser is characterized by various aspects that differ them from the others (Table 1).

At first, they offer higher water recovery with respect to all the other technologies. In addition, despite the adsorption units where problems related to desiccant losses or corrosion can occur, the membrane condensers can be considered as a clean unit operation. However, whether the gaseous stream contains ashes or particles, a pretreatment stage could be required before feeding the membrane condenser. Compared with the dense membrane technology, the main difference can be found in the operating conditions and in the water quality. To promote the permeation of water vapor through dense membranes, a high pressure difference between the two membrane sides is required, implying investment and operational costs related to the presence of compressors or vacuum pump. On the contrary, the purity of the water recovered in membrane condensers can be affected by the possible condensation of contaminants – if present in the gaseous stream – but it is sufficient for cooling tower or boiler makeup. In this context, the possibility of controlling, by opportunely tuning the operating conditions, the condensation of contaminants in the liquid water recovered in the retentate side of the membrane condenser could lead to two different options for its use: as a unit for water recovery,

Membrane Condenser, Table 1 Comparison between membrane condenser and traditional technologies (Brunetti et al. 2013)

	Liquid and solid sorption (Ito 2000)	Cooling with condensation (Folkedahl et al. 2006)	Dense membranes (Isetti et al. 1997)	Membrane condensers (Brunetti et al. 2013)
Water recovery	22–62 %	<70 %	20–40 %	>70 %

minimizing the contaminants content, or as the pretreatment stage in post-combustion capture, forcing most of the contaminants to be retained.

As for the well-known membrane contactors of which membrane condensers represent a special category, many are the challenges that still limit their scaling up from laboratory to industry level.

First of all, the fundamental property that the membrane used in membrane condensers has to show is the high hydrophobicity that avoids the penetration of condensed water into the membrane pores and thus favors the separation of liquid phase from the gaseous one recovered on the permeate side. The hydrophobic character of these membranes is influenced, without any doubt, by the feed conditions. As aforementioned,

in most of the cases, the waste gaseous streams coming out from chimneys of industrial plants contain variable amount of contaminants such as SO_x, NO_x, NH₃, HF, HCl, etc. that on a long-term basis could affect the performance of the membrane condenser, depleting the hydrophobic character of the membrane. The challenge is, thus, to identify materials for making membranes that exhibit excellent resistance and stability toward these components. Actually, these are well represented by PVDF or other superhydrophobic materials such as Hyflon, Teflon, etc. that have the only disadvantage to be quite expensive. The synthesis of new composite membranes where the hydrophobic layer is deposited on a cheaper support can lead to the long-term stability together with a reasonable cost of the unit.

Membrane Contactor (MC)

Alessandra Criscuoli

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Membrane contactors are membrane-based devices that are used to carry out many unit operations like gas–liquid mass transfers, liquid–liquid extractions, and distillation (Drioli et al. 2006). The membranes employed can be both hydrophobic and hydrophilic and their pore size usually ranges from 0.05 to 1 μm . The role of the membrane is to put in contact the involved phases, and the separation is not due to its selectivity, as in the

other membrane operations, but the mass transport occurs at the interface, where the two phases are in contact. In particular, hydrophobic membranes are able to block at their surface polar phases, whereas hydrophilic membranes prevent the passage of nonpolar ones (Fig. 1a, b).

Being each micropore a point of contact for the phases, and being the number of micropores in one membrane extremely high, one of the main advantages of this system, with respect to conventional operations, is the high interfacial area available in small volumes. Furthermore, the possibility of having the interface established at each micropore results in a more stable and better contact between phases. However, for ensuring that no mixing of phases occurs, it is mandatory to do not exceed the so-called breakthrough pressure, that is, the value of pressure at which the phase blocked at the pore mouths starts to penetrate inside the pores. The value of the breakthrough pressure depends on different parameters, like the membrane pore size, the degree of hydrophobicity of the membrane surface, and the fluid properties and can be calculated by Laplace’s equation:

$$\Delta P = (-2\sigma \cos\theta)/r$$

with σ , surface tension of liquid; θ , contact angle between the liquid and the membrane; and r , membrane pore radius.

Different are the membrane operations that belong to the “membrane contactors family” like membrane strippers and scrubbers, supported liquid membranes, phase transfer catalysis, and membrane and osmotic distillation.

Membrane Contactor (MC), Fig. 1 Interface in a hydrophobic (a) and hydrophilic (b) membrane contactor and transport of the species i through the membrane micropore

Membrane Contactor (MC), Table 1 Main advantages and drawbacks of membrane contactors

Main advantages	Main drawbacks
High compactness	Membrane resistance to the mass transport
Known and stable interfacial area	Membrane fouling and loss of membrane properties (like hydrophobicity)
No need of units downstream for phases separation	Operating pressures dependent on the breakthrough pressure value
Flexibility and modularity	

Table 1 summarizes the main advantages and drawbacks of membrane contactors.

Membrane Crystallization (MCR)

Efrem Curcio

Department of Environmental and Chemical Engineering, University of Calabria, Rende, Italy

Membrane operation is aimed at promoting the formation of crystals from supersaturated solutions. The concept of membrane crystallization combines the principles of mass and heat transport through membranes with the theory of heterogeneous nucleation occurring at the interface with polymeric films (Drioli et al. 2005).

Crystallization from solution is driven by supersaturation S , defined as the ratio between the actual solute concentration c and the equilibrium value c^* (saturation):

$$S = \frac{c}{c^*} \quad (1)$$

The selective removal of solvent through appropriate membranes is used to increase the concentration of the solute up to the required supersaturation. Alternatively, membranes are used to selectively feed an antisolvent to induce a demixing effect that generates supersaturation.

Mass transport depends on the specific typology of employed membranes: for microporous hydrophobic membranes (mass transfer in vapor phase under temperature and/or concentration gradient) Dusty Gas Model is applied; for thin film composite membranes (mass transfer in liquid phase under pressure or concentration gradient), Solution-Diffusion Model is employed.

Morphological and physicochemical parameters of the membranes, such as porosity, roughness, or hydrophilic/hydrophobic character, affect significantly the nucleation kinetics. In fact, the formation of a critical nucleus (having 50 % probability to grow or dissolve) is an activate process that imposes the necessity to overcome a Gibbs energy barrier ΔG^* that, for homogeneous nucleation occurring in the bulk of the solution, is given (according to the Classical Nucleation Theory (Drioli et al. 2015)) by:

$$\Delta G_{\text{homogeneous}}^* = \frac{16}{3} \pi \gamma_L^3 \left(\frac{\Omega}{\Delta \mu} \right)^2 \quad (2a)$$

where γ_L is the surface tension of the nucleus-liquid interface, Ω the molar volume of the solute, and $\Delta \mu$ the chemical potential gradient between the crystalline phase and the mother solution. The corresponding critical nucleus R^* is given by:

$$R_{\text{homogeneous}}^* = \frac{2\gamma_L \Omega}{\Delta \mu} \quad (2b)$$

Membrane surfaces act as a promoter of crystallization by lowering the activation barrier to the nucleation stage, thus allowing molecules to aggregate in conditions of supersaturation that would not be adequate for the spontaneous nucleation; therefore, the rate of generation of nuclei is increased. In order to evaluate quantitatively this effect, a constitutive relation expressing the mechanical equilibrium between nucleus-solution (γ_L), nucleus-membrane (γ_i),

Membrane Crystallization (MCr), Table 1 Critical nucleus (R^*) and Gibbs free energy ratio between heterogeneous and homogeneous nucleation ($\Delta G_{\text{heterogeneous}}/\Delta G_{\text{homogeneous}}$) as a function of physicochemical parameters of the membrane

Parameter	R^*	$\Delta G_{\text{heterogeneous}}/\Delta G_{\text{homogeneous}}$
Contact angle (θ), ideal surface	$\frac{2\gamma_L\Omega}{\Delta\mu}$	$(\frac{1}{2} - \frac{3}{4}\cos\theta + \frac{1}{4}\cos^3\theta)$
Porosity (ε)	$\frac{2\Omega\gamma_L}{\Delta\mu} \left[1 - \varepsilon \frac{(1+\cos\theta)^2}{(1-\cos\theta)^2} \right]$	$\frac{1}{4}(2 + \cos\theta)(1 - \cos\theta)^2 \left[1 - \varepsilon \frac{(1+\cos\theta)^2}{(1-\cos\theta)^2} \right]^3$
Wenzel roughness (r)	$\frac{2\Omega\gamma_L}{\Delta\mu} Y$ $Y = \frac{r \cos\theta(1+\cos\theta)-2}{\cos\theta(1+\cos\theta)-2}$	$\frac{1}{4}Y^3(\cos^3\theta - 3\cos\theta + 2)$

Membrane Crystallization (MCr), Fig. 1 Gibbs free energy versus nucleus radius at three different contact angles ($\theta = 90^\circ, 110^\circ, 180^\circ$). Curves reach a maximum in correspondence of the critical radius R^* . Input data: $c/c^* = 1.5$; $\Omega = 1.9 \cdot 10^{-28} \text{ m}^3$; $\gamma_L = 0.004 \text{ J/m}^2$

and solution-membrane (γ_s) interfaces is required. For an ideally solid and smooth surface, Young equation gives:

$$(\gamma_s - \gamma_i) = \gamma_L \cos \theta \tag{3}$$

The introduction of (Eq. 3) into the energy balance of the crystalline phase allows evaluating the reduction of ΔG^* for nuclei formed on a flat sheet membrane. The values of $\Delta G_{\text{heterogeneous}}/\Delta G_{\text{homogeneous}}$ for this case, as well as for porous or rough membranes, are reported in Table 1.

Figure 1 shows that, if nucleation occurs on polymeric membrane with $\theta < 180^\circ$, the work required to generate a critical nucleus on the

surface is higher with respect to nucleation in the bulk of the mother solution ($\theta = 180^\circ$). This phenomenon is known as heterogeneous nucleation.

The possibility to modulate the nucleation rate as a function of morphological and physicochemical properties of the membranes allows to redirect the selective formation of stable or metastable polymorphs. Although identical in their chemical composition, different polymorphs often exhibit important differences in solubility, dissolution rate, stability, melting point, density, and many other properties that significantly affect the efficacy, bioavailability, and safety of active pharmaceutical ingredients. Polymorph selection by membrane crystallization was confirmed by experimental tests carried out on: glycine (selective crystallization of forms α and γ), paracetamol (possibility to discriminate between the monocline stable form of polymorph I and the orthorhombic metastable form of polymorph II), L-glutamic acid (selective crystallization of forms α and β), and L-histidine (selective crystallization of forms A and B) (Drioli et al. 2012).

When investigating nucleation kinetics, an important parameter is the induction time, defined as the time elapsed from the attainment of a given supersaturation up to the formation of critical nuclei. As a general rule, a higher nucleation rate (lower ΔG^*) results in a shorter induction time. This is particularly evident in the crystallization of proteins: macromolecules display a rather asymmetric and weak bonding configuration at their surfaces and tend to aggregate in n-mers that diversify the shape and size of lattice units, thus making ordered attachment for growing units less probable.

Experiments carried out on various hydro-soluble proteins (such as lysozyme, trypsin, β -glucosydase) showed the possibility to obtain a crystalline product in shorted times with respect to those measured when using conventional vapor diffusion techniques under the same supersaturation level (Curcio et al. 2010). Moreover, X-ray diffraction analysis by synchrotron radiation confirmed a high structural order of crystals grown on microporous membranes (i.e., polypropylene). Crystallization experiments on metals-proteins have also resulted in a new orthorhombic form P21212 of the complex Lysozyme- Co^{2+} .

In order to understand the effect of the chemistry of surface on the heterogeneous nucleation, Curcio et al. (2014) investigated the mechanisms of acetaminophen (ACM) crystal formation due to specific solute-surface interactions on polydimethylsiloxane (PDMS) with siloxane functional groups $\text{Si} - \text{O} - \text{Si}$ forming the backbone of silicones, partially fluorinated elastomer polyvinylidenedifluoride (PVDF), polystyrene (PS) having weak electron-donor phenyl rings, poly(*n*-buthyl methacrylate) (P *pu* BMA) showing ester functionality, polyimide (PI) that includes both hydrogen-bond acceptor imide functionality and carbonyl groups, ethylene/acrylic acid (EAA) copolymer with only the carboxyl moiety. Power X-ray Diffraction analysis showed the occurrence of preferred orientation (PO) depending on the strength of the intermolecular interactions occurring at the polymer-crystal interface during nucleation: from nonspecific adsorption (PDMS, PnBMA, and PS) to oriented arrangement of molecules in the crystalline lattice (EAA, PI, and PVDF) (Curcio et al. 2014).

Definition

Controlling polymorphism with membrane-based crystallizers: application to form I and II of paracetamol. Selective glycine polymorph crystallization by using microporous membranes. Effect of supersaturation control and heterogeneous nucleation on porous membrane surfaces in the crystallization of L-glutamic acid polymorphs.

Many substances can exist in solid crystalline state as several phases, a phenomenon named polymorphism. Each polymorph is characterized by its specific physical properties, like solubility, dissolution rate, thermal and mechanical stability, optical properties, etc. Therefore, each form represents a specific material, different to some extent from the other phases of the same substance, and this has remarkable implications for its specific utilization in industrial, technological, and scientific applications. Among the different phases, the relative stability in a specific condition is ruled by thermodynamics, as described by the classical nucleation theory (CNT) (Kashchiev 2001). However, the phase that will be effectively obtained depends on kinetics (Ostwald 1987). This is because a competition between the thermodynamic and kinetic control of the nucleation

phase, in combination with the relative growth rates of the different polymorphs, will affect the final outcome of the crystallization process.

In a membrane crystallizer, this kind of control can be achieved by controlling the composition of the crystallizing solution through the management of the transmembrane flux. This provides an opportunity to systematically affect the rate of variation of the supersaturation which, in turn, affects the polymorphic composition of the precipitate. As this control can be produced very precisely, by fine-tuning the operating conditions and/or by choosing the opportune membrane properties, selective polymorph crystallization is an important possibility available with membrane crystallization technology (Di Profio et al. 2007a). Namely, during a crystallization process, when the least stable structure (or a mixture of nuclei of the different polymorphs) forms following an Ostwald-like behavior, the relative growth rates of the different phases with respect to the supersaturation generation rate will fix which form will effectively be grown. When the rate of variation of supersaturation is low, due to the low evaporation rates through the membrane, if nuclei of the more stable structure have time to grow at the expense of the less stable forms via solvent-mediated transfer of solute, a “thermodynamic control” and the more stable polymorph will selectively (or prevalently) be obtained. However, for higher evaporation rates, the increase in the metastable zone width induces nucleation at higher values of supersaturation. In this situation, the conversion from the metastable to the stable phase could not be fast enough with respect to the growth of the former, so that the growth of the kinetically favored form (metastable), which might be also the first to appear according with the Ostwald rule of stages, is observed. In this case the overall process is “kinetically controlled” (Di Profio et al. 2007b). Accordingly, high control of the membrane-based process provides the possibility to induce polymorphic selection during crystallization by switching between a kinetic and a thermodynamic control of the nucleation stage thus allowing the production of either a metastable or a stable structure (Di Profio et al. 2009).

Membrane Distillation (MD)

Francesca Macedonio
 Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy
 Department of Environmental and Chemical Engineering, University of Calabria, Rende, Italy

Membrane distillation (MD) is a thermal membrane operation known for more than 50 years (first patent was filed by Bodell on 3 June 1963 (Findley 1967); first MD paper was published 4 years later by Findley (Bodell 1963)). During the last years, the number of papers published on MD and the research groups focusing on MD studies have been increasing (Fig. 1).

MD has great potential as a concentration process at low temperature and energy with respect to

Membrane Distillation (MD), Fig. 1 Number of the papers published in *Journal of Membrane Science* on MD field each year up to September 2011 (Drioli et al. 2012)

Membrane Distillation (MD), Fig. 2 General scheme of the MD process: aqueous solution on feed side whereas four different solutions can be realized on permeate side (aqueous solution or air gap or vacuum or sweeping gas) (Lawson and Lloyd 1997)

M

conventional processes, such as distillation and reverse osmosis (RO). MD allows the separation of volatile components from solutions. If the solutions contain nonvolatile components, it is possible to remove solvent by concentrating the solutions.

In MD, one side (feed side) of a hydrophobic membrane is brought into contact with a heated, aqueous feed solution. The hydrophobic nature of

the membrane prevents penetration of the aqueous solution into the pores, resulting in a vapor–liquid interface at each pore entrance. Here, volatile compounds evaporate, diffuse and/or convect across the pores, and are condensed on the opposite side (permeate) of the system (Fig. 2). The driving force of the process is linked to the vapor-pressure gradient between the two membrane sides.

The documented and expected benefits resulting from MD are as follows:

- The nature of the driving force and the hydro-repellent character of the membrane allow the theoretically complete rejection of nonvolatile components such as macromolecules, colloidal species, and ions.
- Lower temperatures with respect to those usually used in conventional distillation column are sufficient to establish interesting transmembrane flux, with consequent reduction of energy costs, thus allowing the efficient recycle of low-grade waste heat streams as well as the use of alternative energy sources (solar, wind, or geothermal).
- Lower pressures with respect to those usually utilized in RO because the required operating pressures are of the order of few hundred kPa. Lower operating pressure translates to lower equipment costs, increased process safety, and possibility of using plastic equipment, thus reducing or avoiding erosion problems.
- If compared to RO process, MD permeate flux is only slightly affected by the concentration of the feedwater, and thus, productivity and performance remain roughly the same for high concentration feedwaters. This means that MD can be preferentially employed whenever elevated permeate recovery factors or high retentate concentrations are requested. On the contrary, in MD temperature polarization, similar to concentration polarization, arises from heat transfer through the membrane and it is often the rate-limiting step for mass transfer.
- Since MD membranes act merely as a support for a vapor–liquid interface, they do not distinguish between solution components on a chemical basis, do not act as a sieve, and do not react electrochemically with the solution; they can be fabricated from almost any chemically resistant polymers with hydrophobic intrinsic properties, such as polytetrafluoroethylene (PTFE), polypropylene (PP), and polyvinylidene difluoride (PVDF). This characteristic increases membrane life. New amorphous perfluoro polymers (e.g., Hyflon, Teflon) can be also utilized neglecting their

still high costs. On the other hand, MD performance (in particular the transmembrane flux and the heat loss by conduction through the membrane) is intrinsically affected by the structure of the membrane in terms of thickness, porosity, mean pore size, pore distribution, and geometry.

- Membrane fouling is less problematic in MD than in other membrane separations because (i) the pores are relatively large compared to RO/UF pores; (ii) the process liquid cannot wet the membrane – therefore, fouling layers can be deposited only on the membrane surface but not in the membrane pores; and (iii) due to the low operating pressure of the process, the deposition of aggregates on the membrane surface would be less compact and only slightly affect the transport resistance.
- On the contrary, one problem that can arise in MD is the *membrane wetting* which occurs when the liquid penetrates into the membrane pores. Once a pore has been penetrated, it is said to be “wetted” and the membrane must be completely dried and cleaned before the wetted pores can once again support a vapor–liquid interface.

In MD process both heat and mass transfer phenomena occur through the membrane. Figure 3 illustrates the possible heat transfer resistances in MD with an electrical analogy.

Heat is first transferred from the heated feed solution of uniform temperature T_f , across the thermal boundary layer to the membrane surface at a rate $Q = h_f \cdot \Delta T_f$. At the surface of the membrane, liquid is vaporized and heat is transferred across the membrane at a rate $Q_v = h_v \cdot \Delta T_m = N \cdot \Delta H_v$ (where N is the rate of mass transfer and ΔH_v is the heat of vaporization). Additionally, heat is conducted through the membrane material and the vapor that fills the pores at a rate $Q_m = h_m \cdot \Delta T_m$ where $h_m = \varepsilon \cdot h_{mg} + (1 - \varepsilon)h_{ms}$ (ε is the membrane porosity; h_{mg} and h_{ms} represent the heat transfer coefficients of the vapor within the membrane pores and the solid membrane material, respectively). Conduction is considered a heat loss mechanism because no corresponding mass transfer takes place. Total heat transfer

Membrane Distillation (MD), Fig. 3 Heat transfer resistances in MD

across the membrane is $Q = Q_v + Q_m$. Finally, as vapor condenses at the vapor–liquid interface, heat is removed from the cold-side membrane surface through the thermal boundary layer at a rate $Q = h_p \cdot \Delta T_p$.

The overall heat transfer coefficient of the MD process is given by

$$\frac{1}{U} = \frac{1}{h_f} + \frac{1}{h_m + h_v} + \frac{1}{h_p} = \frac{1}{h_f} + \frac{1}{\left(\frac{K_g \cdot \varepsilon + K_m(1 - \varepsilon)}{\delta}\right) + \left(\frac{N \cdot \Delta H_v}{T_{fm} - T_{pm}}\right)} + \frac{1}{h_p} \quad (1)$$

where each h and each T represent the corresponding heat transfer coefficients and temperatures shown in Fig. 3.

The total heat transferred across the membrane is given by

$$Q = U \cdot \Delta T \quad (2)$$

Equation 1 illustrates the importance of minimizing the boundary layer resistances (maximizing the boundary layer heat transfer coefficients). A commonly used measure of the magnitudes of the boundary layer resistances relative to the total heat transfer resistance of the system is given by the temperature polarization coefficient (TPC):

$$TPC = \frac{T_{fm} - T_{pm}}{T_f - T_p} \quad (3)$$

- If $TPC \rightarrow 1$, the MD system is well designed, and it is limited by mass transfer.
- If $TPC \rightarrow 0$, the MD system is poorly designed and it is limited by heat transfer through the boundary layers.

In literature, the recommended range of TPC is from 0.4 to 0.7 for well-designed systems (Lawson and Lloyd 1997).

The boundary layer heat transfer coefficients are almost always estimated from empirical correlations such as the following:

- Sieder–Tate correlation for turbulent liquid flow inside circular tubes

$$h = \frac{Nu \cdot K^T}{d}, \quad Nu = 0.023 \cdot Re^{0.8} \cdot Pr^{1/3}.$$

$$\phi_\mu^{0.14} \text{ or } \frac{hd}{K^T} = 0.023 \cdot \left(\frac{dG}{\mu}\right)^{0.8} \cdot \left(\frac{c_p \mu}{K^T}\right)^{1/3} \cdot \left(\frac{\mu}{\mu_w}\right)^{0.14} \quad (4)$$

where d is the tube diameter, K^T is the thermal conductivity of the liquid, G is the mass velocity equal to $w/S = \langle \rho v \rangle$, μ is the bulk liquid viscosity, μ_w is the liquid viscosity at the wall, c_p is

the liquid heat capacity, and ϕ_μ is the heating/cooling correction factor.

Equation 4 should be used for $Re > 6000$ and for tubes with large ratios L/d (where L is the tube length). For short tubes ($L/d < 50$), several corrections are available, including $\frac{h}{h_\infty} = 1 + \left(\frac{d}{L}\right)^{0.7}$

where h_∞ is the heat transfer coefficient given by Eq. 4.

For the case of a noncircular flow channel, these correlations can still be used if the equivalent diameter d_e of the flow channel is substituted:

$$d_e = 4 \cdot r_H = 4 \cdot \frac{S}{L_p} = 4 \cdot \frac{\text{cross-sectional area of the flow channel}}{\text{length of the wetted perimeter of the flow channel}} \quad (r_H = \text{hydraulic radius})$$

- Sarti correlation for laminar liquid flow in circular tubes with constant wall temperature:

$$Nu = 3.66 + \frac{0.067 \cdot Gz}{1 + 0.04 \cdot Gz^{2/3}} \quad \text{where}$$

$$Gz = \frac{\dot{m} c_p}{K^T L} \quad (5)$$

where G_z is the Graetz number, $\dot{m}$ is the mass flow rate, c_p is the liquid heat capacity, K^T is the liquid thermal conductivity, and L is the length of the tubes.

However, several empirical correlations exist which allow to estimate the boundary layer heat

transfer coefficients for other geometries and heat transfer mechanisms.

The heat transfer across the membrane has been already described. For what concerns the heat transferred by convection within the membrane pores, this can be also considered but is negligible because convection accounts for, at most, 6 % of the total heat lost through the membrane and only 0.6 % of the total heat transferred across the membrane (Lawson and Lloyd 1997).

Regarding mass transfer, Fig. 4 illustrates the possible mass transfer resistances in MD using an electrical analogy.

The resistances shown in Fig. 4 are arranged as described by the dusty gas model (DGM), which

Membrane Distillation (MD), Fig. 4 Mass transfer resistances in MD

is a general model for mass transport in porous media.

- *Mass transfer across boundary layers*

A mass balance across the feed side boundary layer yields the relationship between molar flux N , the mass transfer coefficient k_x , and the solute concentrations c_m and c_b at the interface and in the bulk, respectively (Curcio and Drioli 2005; Mya Tun et al. 2005):

$$\frac{N}{\rho} = k_x \ln \frac{c_m}{c_b} \quad (6)$$

where ρ is the solution density.

The method that is used in literature to determine the mass transfer coefficient is to employ an analogy between heat and mass transfer. Therefore, Eqs. 4 and 5 can be used to estimate boundary layer mass transfer coefficients by substituting the Sherwood number for the Nusselt number, the Schmidt for the Prandtl, and the mass transfer Graetz number for its heat transfer form. In general, the used correlations are as follows:

$$Sh = \alpha Re^\beta Sc^\gamma \quad (7)$$

where Sh = Sherwood number = $(k_x d_h)/D$ (d_h hydraulic diameter, D diffusion coefficient in the liquid), Sc = Schmidt number = $\mu/(\rho D)$ (μ is the bulk liquid viscosity; ρ is the solution density), and Gz_M = mass transfer Graetz number = $Gz_M = \frac{\dot{m}}{\rho D_{AB} L}$ ($\dot{m}$ is the mass flow rate; L is the tube length).

As a result of the solvent transmembrane flux across the membrane, when aqueous solutions containing nonvolatile solutes are considered, the concentration of the nonvolatile solutes at the membrane surface (C_{Bm}) becomes higher than that at the bulk feed (C_{Bb}) with time as long as the separation process is taking place. Almost 100 % of separation is obtained. In this case, care must be taken as supersaturation states may eventually be achieved affecting the efficiency of the membrane process. The term concentration polarization coefficient (CPC) is defined to quantify the mass transport resistance

within the concentration boundary layer at the feed side as follows:

$$CPC = \frac{C_{Bm}}{C_{Bb}} \quad (8)$$

The increased concentration of nonvolatile compounds next to the membrane surface would have the influence of reducing the transmembrane flux due to the establishment of concentration polarization (CP) layer at the feed side that acts as a mass transfer resistance to the volatile molecule species (water). Fortunately, in MD process, the low to moderate flow rates and high heat transfer coefficients reduce the impact of concentration polarization, which is lower than that of the temperature polarization effect (Laganà et al. 2000; El-Bourawi et al. 2006; Drioli et al. 1999; Srisurichan et al. 2006). In fact, boundary layers next to the membrane can contribute substantially to the overall transfer resistance; heat transfer across the boundary layers is often the rate-limiting step for mass transfer in MD because a large quantity of heat must be supplied to the membrane surface to vaporize the liquid and because the membrane fabrication technology has improved in the last decades so much that MD process has shifted away from being limited by mass transfer across the membrane to being limited by heat transfer through the boundary layers on either side of the membrane.

- *Mass transport through the membrane pores*

As stated earlier, the mass transfer process in MD is driven by the imposed vapor-pressure gradient between both sides of the membrane. The mass transport mechanism is governed by three basic mechanisms known as Knudsen diffusion, Poiseuille flow, and molecular diffusion or the combinations between them known as transition mechanism (excluding surface diffusion, negligible in MD because, by definition of the MD phenomenon, molecule—membrane interaction is low and the surface diffusion area in MD membranes is small compared to the pore area).

The dusty gas model is usually used as a general model taking into account the latter basic mechanisms (Lawson and Lloyd 1997; Curcio and Drioli 2005; El-Bourawi et al. 2006):

$$\frac{N_i^D}{D_{ie}^k} + \sum_{j=1 \neq i}^n \frac{p_j N_i^D - p_i N_j^D}{D_{ije}^0} = \frac{-1}{RT} \nabla p_i \quad (9)$$

$$N_i^V = -\frac{\varepsilon r^2 p_i}{8 R T \tau \mu} \nabla P \quad (10)$$

$$D_{ie}^k = \frac{2 \varepsilon r}{3 \tau} \sqrt{\frac{8 R T}{\pi M_i}} \quad (11)$$

$$D_{ije}^0 = \frac{\varepsilon}{\tau} D_{ij}^0 \quad (12)$$

where N^D is the diffusive flux, N^V is the viscous flux, D^k is Knudsen diffusion coefficient, D^0 is the ordinary diffusion coefficient, p_i is the partial pressure of the component i , P is the total pressure, M_i is the molecular weight of component i , r is the membrane pore radius, ε is the membrane porosity (assuming the membrane consists of uniform cylindrical pores), μ is the fluid viscosity, and τ is the membrane tortuosity. The subscript “e” is indicative of the effective diffusion coefficient function of the membrane structure.

There is only one problem with the application of the DGM to MD, and that lies in the fact that MD is a non-isothermal process. The DGM was derived for isothermal flux, but has been successfully applied to non-isothermal systems via the inclusion of terms for thermal diffusion and thermal transpiration. However, it is easily shown (Lawson and Lloyd 1997) that these terms are negligible in the MD operating regime, and T_{avg} in the membrane is used in place of T in the DGM equations.

Regardless of which mechanism is involved in the mass transportation process, the molar flux, N , must be proportional to the vapor-pressure difference across the membrane:

$$N = C \cdot \Delta P$$

where ΔP is the vapor-pressure difference across the membrane (function of temperatures and compositions at the membrane surface) and C is the membrane distillation coefficient that can be obtained experimentally. C is a function of temperature, pressure, and composition within the membrane as well as membrane structure and depends on the MD configuration employed as well as on the Knudsen number (Kn , ratio of the mean free path of the transported gas molecules (λ) through the membrane pores to the mean pore diameter of the membrane (d)). In fact, Kn number determines the physical nature of flow through membrane pores, and since the membranes used in MD exhibit pore size distribution, more than one mechanism may occur through the membrane.

Whereas on feed side only an aqueous solution can be present, the nature of the permeate can be different and gives origin to the four basic MD configurations:

- Direct contact MD (DCMD), in which the permeate is in liquid phase and, therefore, the membrane is on both sides *directly* in contact with aqueous solutions
- Vacuum MD (VMD), in which the vaporized solvent is recovered by vacuum and condensed, if needed, in a separate device
- Air gap MD (AGMD), in which an air gap is interposed between the membrane and a condensation surface
- Sweeping gas MD (SGMD), in which a stripping gas is used as a carrier for the removal of the produced vapor (Fig. 5)

The type of employed MD depends upon permeate composition, flux, and volatility:

- SGMD and VMD are typically used to remove volatile organic or dissolved gas from an aqueous solution.
- Because AGMD and DCMD do not need an external condenser, they are best suited for applications where water is the permeating flux.
- The DCMD configuration, which requires the least equipment and is simplest to operate, is

Membrane Distillation

(MD), Fig. 5 Common configurations of the membrane distillation process that may be utilized to establish the required driving force (El-Bourawi et al. 2006)

**Membrane Distillation**

(MD), Fig. 6 Basic channel arrangement and temperature profile for PGMD (Winter et al. 2011)

best suited for applications such as desalination or the concentration of aqueous solutions (orange juice), in which water is the major permeate component.

- AGMD, which is the most versatile MD configuration, can be applied to almost any applications.

Some new configurations with improved energy efficiency, better permeation flux, or smaller footprint have been proposed such as material gap

membrane distillation, multi-effect membrane distillation, multi-effect vacuum membrane distillation, permeate gap membrane distillation, and hollow fiber multi-effect membrane distillation.

Permeate gap membrane distillation (PGMD) is an enhancement of DCMD in which a third channel is introduced by an additional non-permeable foil (Fig. 6).

One significant advantage of PGMD is the separation of the distillate from the coolant. Therefore the coolant can be any other liquid,

such as cold feedwater. This offers the opportunity to integrate an efficient heat recovery system.

Multi-effect membrane distillation (MEMD) is based on the concepts of multi-stage and multi-effect distillation for seawater desalination. The cold feed solution is placed beneath the condensation surface as a coolant to condense the permeated vapors as well as to gain heat at the same time. The pre-heated feed solution is further heated before it enters the feed channel.

Vacuum-multi-effect membrane distillation (V-MEMD) is a modified form of VMD that integrates the concept of multi-effect distillation into the VMD. As a general principle of the process, the vapors produced in each stage are condensed during the subsequent stages. Vapors are generated in steam raiser working under vacuum by exchanging the heat provided by external source. The vapors are introduced in first stage where these are condensed by exchanging the heat with feed via a foil. The vapors generated in first stage are transported through the membrane and collected on the foil in the second stage. It has been claimed that these modules have excellent gained to output ratio which is crucial parameter for industrial applications (Zhao et al. 2013). A condenser is used to condense the vapors generated in final stage. The vapor pressure in each stage is less than its preceding stage.

Material gap membrane distillation (MGMD) consists of filling the gap between the membrane and the condensation plate with different materials having different characteristics such as polyurethane (sponge), polypropylene mesh, sand, and deionized water in order to increase transmembrane flux with respect to AGMD.

Osmotic distillation (OD) represents another extension of the MD concept: a microporous hydrophobic membrane separates two aqueous solutions that are kept in contact at different solute concentrations; this difference in activity causes a vapor-pressure difference that activates mass transport through the membrane. Because OD operates essentially at room temperature, it is appropriate for applications in the agro-food industry (such as in integrated membrane system for the clarification and the concentration of citrus and carrot juices that has been proposed as an

alternative and efficient approach to the traditional techniques currently in operation), in pharmaceutical biotechnology, and medicine (more information can be found in Drioli et al. (2006), Drioli et al. (2015)).

To date, the slow progress of MD has been related with the unavailability of appropriate membranes and modules for MD applications, high energy consumption with respect to RO that increases the overall energy demand, membrane wetting, and low flux. However, thanks to the recent and growing extensive research activities carried out in various areas of MD, the process has become much more attractive due to the availability of better membranes and to the possibility to utilize alternative energy sources in niche applications.

Membrane Distillation Applications

Francesca Macedonio

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Department of Environmental and Chemical Engineering, University of Calabria, Rende, Italy

Membrane distillation (MD) is a non-isothermal process that allows the separation of volatile components from solutions. If the solutions contain nonvolatile components, it is possible to remove solvent by concentrating the solutions. MD has been applied for separation of nonvolatile components from water like ions, colloids, and macromolecules (El-Bourawi et al. 2006; Lawson and Lloyd 1996, 1997; Mengual and Pena 1997; Khayet et al. 2003, 2006; Sudoh et al. 1997; Drioli et al. 1986; Zolotarev et al. 1994); for the removal of trace volatile organic compounds from water such as benzene, chloroform, and trichloroethylene (Lawson and Lloyd 1997; Duan et al. 2001; Banat and Simandl 1996, 2000; Sarti et al. 1993; Qureshi et al. 1994; Banat and Al-Shannag 2000); or for the extraction of other organic compounds such as alcohols from dilute aqueous solutions (Lawson and Lloyd 1997; Garcia-Payo et al. 2000; Banat and Simandl 1999; Bandini et al. 1997; Bandini and Sarti 1999). As a

consequence, MD is suited for both concentration of aqueous solutions and water production. In fact, MD has been applied for water desalination where near 100 % rejection of nonvolatile ionic solutes is easily achieved (an example can be found in the European-funded project MEDINA (Drioli et al. 2011)), wastewater treatment and food processing (concentration of juice and raw cane sugar), and biomedical applications (such as water removal from blood and treatment of protein solutions) (El-Bourawi et al. 2006). Moreover, thanks to its characteristic to work at lower temperatures with respect to those usually used in thermal processes and thus allowing the efficient use of alternative energy sources (solar, wind, or geothermal), MD has been considered a valid desalination operation in arid areas with abundant solar energy available.

However, a lot of other interesting applications of MD have been explored due to less fouling tendency of the process and the potential to treat complex feed solutions. Separation of azeotropic aqueous mixtures such as alcohol–water mixtures, concentration of radioactive solutions and application for nuclear desalination, wastewater treatment in which a less hazardous waste can be discharged to the environment specially in textile waste treatment that is contaminated with dyes, concentration of coolant (glycol) aqueous solutions, treatment of humic acid solutions, pharmaceutical wastewater treatment, and in areas where high-temperature applications lead to degradation of process fluids can be attractive (Banat and Simandl 1996).

In addition, due to the chemical stability of the employed membranes, MD can also be applied for the concentration of acids (Tomaszewska 1993; Tomaszewska et al. 1995; Tang et al. 2003). A list of innovative and potential uses of MD for various applications mentioned in the recent literature is provided in Table 1.

More recently membrane distillation has been also used in membrane bioreactor configuration (MDBR) for the treatment of industrial and municipal used waters, in order to retain effectively small size and persistent contaminants (Phattaranawik et al. 2008). The possibility to combine MD with the production of high-quality

crystals extracted from the brine of nanofiltration (NF) and reverse osmosis (RO) is particularly interesting and promising as suggested in Drioli et al. (2011), Macedonio et al. (2007), and Macedonio and Drioli (2010). Moreover, membrane distillation can be also utilized in integrated system with pressure retarded osmosis (PRO) or reverse electrodialysis (RED) for utilizing salinity gradient for energy production (the so-called blue

energy). An example can be found in the Megaton project (Kurihara and Hanakawa 2013) in Japan and in the SeaHero project (Kim et al. 2009, 2011) in South Korea. In the last part of these two projects, hybrid systems with MD and PRO units have been proposed for the extraction of valuable resources from the brine, the minimization of the environmental impact of the brine, and the recovery of energy.

Membrane Distillation Bioreactor (MDBR)

Tony Fane

School of Chemical Engineering, The University of New South Wales, Sydney, NSW, Australia
Singapore Membrane Technology Centre,
Nanyang Technological University, Singapore, Singapore

The Membrane Distillation Bioreactor (MDBR) combines a wastewater bioreactor with membrane distillation (MD) (Fane et al. 2012). It is shown schematically in Fig. 1. The MDBR is a member of the Membrane Bioreactor (MBR) family but with important differences from the conventional MBR. The conventional MBR uses microporous membranes, either microfiltration (MF) or ultrafiltration (UF), to retain biomass, or mixed liquor, within the reactor. The MDBR employs a MD membrane to retain the mixed liquor and provide the treated wastewater. The MDBR membranes can be either submerged in the bioreactor or located in a sidestream. An elevated temperature, typically 50–60 °C, is used to drive water across the membrane and this means that thermophilic biomass are required. In addition the hydrophobic membrane retains nonvolatile salts that accumulate in the reactor. Therefore the MDBR biomass need to be salt tolerant (halotolerant). The MDBR concept provides a “high retention” MBR, wherein low molecular weight molecules do not leave the reactor through the membrane, as they would through MF or UF membranes in the conventional MBR. This means that the organic retention time (ORT) in the MDBR can be significantly longer than the hydraulic retention time

Membrane Distillation Bioreactor (MDBR), Fig. 1 Membrane distillation bioreactor

(HRT) and recalcitrant organics are given longer to degrade. In contrast the conventional MBR has ORT equal to HRT. The MDBR, in common with other MBRs, typically has a small “bleed”, or wastage, stream to maintain a steady-state concentration of mixed liquor suspended solids (MLSS). The proportion wasted daily determines the “sludge retention time” (SRT); for example 5 % removal per day gives SRT of 20 days, 10 % removal gives SRT of 10 days etc. The accumulation of nonvolatile and nonbiodegradable species in the reactor is determined by the ratio of SRT/HRT, which represents the concentration factor and could exceed 20x. Retained salts can reach significant levels, but with acclimatization the biomass can cope.

The MDBR can provide a high-quality treated water, suitable for reuse. This is due to the unique separation properties of the typical MD membrane. In common with other membrane processes, the MDBR can experience fouling, and this can be controlled by bubbling and occasional cleaning. Experience indicates that the fouling is usually a combination of inorganic scale (calcium salts) and biofouling. Fluxes of the order of 10 l/m²h can be sustained.

The MDBR is a developmental concept and not widely used. However it has been demonstrated in the petrochemical industry (Khaing et al. 2010) providing a highly treated water, and driven by waste heat. Other target industries include food and pharmaceutical wastewaters.

Another opportunity could be water reclamation where an analysis shows a 30 % lower electrical energy usage than a combined MBR and RO process. Recently the MDBR has been operated under anaerobic conditions with the generation of biogas.

Membrane Distributor

Juergen Caro
Institute of Physical Chemistry and
Electrochemistry, Leibniz University, Hannover,
Germany

Synonyms

Distributor Reactor

A membrane distributor is a special type of a membrane reactor with “distributed” feeding,

i.e., one or several reactants are fed through a membrane to the reaction zone (Dittmeyer and Caro 2008; Caro 2010). In general, a selectivity increase can be expected. On the one hand, a more uniform concentration of the dosed reactants can be expected. On the other hand, also a nonuniform but specific shape of a concentration profile can be realized which can be beneficial for kinetic reasons. Further, the total amount of reactants that can be supplied without exceeding the threshold for safe operation can also be increased. One additional effect observed when applying a distributed feed along the reactor is an increasing flow rate downstream which shortens the contact time on catalytic sites.

The concept of “membrane distributor reactor” does not necessarily require a selective membrane, provided that the transmembrane flux can be properly controlled by the differential pressure. Therefore, the distributed feeding can be either (i) selective or (ii) nonselective:

- (i) **Selective supply:** There are numerous examples for the selective feed supply. Examples are the hydrogen supply through a hydrogen-selective membrane (Pd, zeolite, MOF, carbon, etc.) in partial hydrogenations or the oxygen supply through an oxygen-selective membrane (perovskite, other oxygen-transporting ceramics) in partial hydrocarbon oxidations. In both cases, improved selectivities can be expected since the hydrogenations or oxidations take place at constant and low hydrogen/oxygen partial pressure in, e.g., axial direction of a tubular membrane reactor.
- (ii) **Nonselective supply:** In the strong sense of a membrane reactor, only the selective feeding fulfills the definition of a membrane reactor as a device combining membrane-based separation and a chemical reaction in one unit (Koros et al. 1996). However, also in this case, the transmembrane flux can be tuned by the pressure difference, thus controlling the partial pressure of the reactants resulting in a higher selectivity. As an example, porous membranes can be used to distribute oxygen or air in a nonselective manner to the reactor providing a low and uniform oxygen partial

pressure along the reactor. This avoids large differences in the reaction rate and selectivity along the reactor. The use of porous membranes as air distributor is usually not combined with an oxygen enrichment.

Membrane Dryer

Alessandra Criscuoli

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Membrane Dryer is a membrane-based system able to dry solid particles contained in liquid streams while producing a particle-free liquid (Drioli et al. 2014, Criscuoli et al. 2016). The main principles are those of membrane distillation: the liquid stream (feed) to be treated is in contact with one side of a microporous membrane and the liquid permeates as vapor, thanks to a driving force that can be established across the membrane in different ways: by applying vacuum, by creating an air gap, or by sending a cold liquid or a sweep gas (Fig. 1).

Membranes to be used must be:

1. Microporous;
2. Hydrophobic (for aqueous feeds);
3. Hydrophilic (for organic feeds);
4. With a pore size smaller than the solid particle size.

Membrane Dryer,
Fig. 1 Scheme of a
 membrane dryer

Main advantages with respect to conventional drying systems are:

1. The ability to work with feeds of different concentration (dilute or concentrated feeds)
2. The ability to work with feeds containing solid particles of different size
3. The production of particle-free liquid without the need of a separation step downstream
4. The modularity, flexibility, easy scale-up and scale-down, and low footprint (all typical advantages of membrane processes)

Membrane Emulsification

Emma Piacentini

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Membrane emulsification is a drop-by-drop emulsification method in which the dispersed phase

Membrane Emulsification,
Fig. 1 Droplet formation
 and forces acting at the
 membrane pore level

(as a pure liquid or an emulsion) is pressed through microporous membranes to form droplets at the membrane surface pore level which are collected in the continuous phase (Fig. 1).

The forces acting on a droplet at the membrane pore level include: (i) detaching forces, driving droplets off the pore, and (ii) retaining forces, holding droplets on the pore (Fig. 1, Table 1; Giorno et al. 2009).

The drag force (F_D) is created by the continuous phase flowing parallel to the membrane surface; the buoyancy force (F_{BG}) is due to the density difference between the continuous phase and the dispersed phase; the inertial force (F_I) is caused by the dispersed phase flow moving out from the pore outlet; the dynamic lift force (F_L) results from the asymmetric velocity profile of the continuous phase near the droplet; static pressure (F_{SP}) force is due to the pressure difference between the dispersed phase and the continuous phase at the membrane surface; the interfacial tension force (F_γ) is provided by the effects of dispersed phase adhesion around the edge of the

Membrane Emulsification, Table 1 The forces acting on a droplet at the membrane pore level

Detaching forces		Retaining forces	
Drag force	$F_d = \frac{3}{2} k_x \pi \tau_{c,s} d_d^2$	Interfacial tension	$F_\gamma = \pi d_p \gamma$
Buoyancy force	$F_B = \frac{1}{6} \pi g \Delta \rho d_d^3$		
Lift force	$F_L = 0.761 \frac{\tau_{c,s}^{1.5} \rho_c^{0.5}}{\mu_c} d_d^3$		
Static pressure	$F_{sp} = \frac{\gamma}{d_p} \pi d_d^2$		
Inertial force	$F_I = \rho_d \left(\frac{d_d}{\varepsilon} \right) A_N$		

d_d droplet diameter, A_N cross-sectional area of the droplet neck, k_x equal to 1.7 and takes into account the wall correction factor for a single sphere touching an impermeable wall, ε membrane porosity, $\tau_{c,s}$ wall shear stress, γ dynamic interfacial tension, ρ_c density of the continuous phase, ρ_d density of the dispersed phase, μ_c viscosity of the continuous phase, $\Delta \rho$ the difference between continuous and dispersed phase density

pore opening. In the case of “moving membrane” emulsification, additional forces have to be considered. For rotating membrane emulsification, the additional forces are the centrifugal force to aid droplet detachment and the tangential velocity differences between the droplet and the continuous phase. For an oscillating membrane system where the membrane is transversally excited, an additional drag force and an inertial force appear in the direction parallel to the membrane.

The influence of different parameters on particle diameter (D_p), particle size distribution (PSD), and process productivity (volumetric flux of the disperse phase normalized by the actual membrane area and time (J_d)) is summarized in Table 2.

Table 2 demonstrates that:

Particle size is significantly influenced by:

- *The pore size of the membrane.* The particle size increases linearly with the membrane pore size (Katoh et al. 1996).
- *The surface wetting properties of the membrane.* Membranes unwetted by the dispersed phase allow the generation of droplets with particle size controlled by the membrane pore size. On the contrary, the spread of the dispersed phase on the membrane as a consequence of the wettability determines the uncontrolled production of the droplets (Piacentini et al. 2014).
- *The wall shear stress.* The particle size becomes smaller as the wall shear stress increases and the influence is greater for low wall shear stresses and more effective

Membrane Emulsification, Table 2 The influence of different parameters on particle diameter (D_p), particle size distribution (PSD), and process productivity (J_d)

☆☆☆ very significant; ☆☆ significant; ☆ not significant

for smaller membrane pores size (Katoh et al. 1996).

- *The emulsifier type and concentration.* The faster emulsifier molecules adsorbed at newly formed interfaces, the smaller the emulsion droplets due to the influence of emulsifier on the interfacial tension. Particle size decreased as a function of emulsifier concentration as the interfacial tension had decreased to a constant (Schröder et al. 1998).

Particle size distribution is significantly influenced by:

- *Pore size distribution.* Uniform particle size distribution is obtained with membranes with uniform pore size distribution.
- *Distance between pores and porosity.* The controlled pore distance and the lower membrane porosity avoid droplet coalescence at the membrane pore level (Kobayashi et al. 2002).
- *Wall shear stress.* The faster is the detachment of the droplets at the membrane pore level, the lower is the droplet coalescence at the membrane surface.

Productivity is significantly influenced by:

- *Pore size, porosity, transmembrane pressure, and viscosity of dispersed phase.* As demonstrated by the Poiseuille equation, the dispersed phase flux is enhanced through the use of membranes with larger pore sizes and higher pore density, and it is proportional to the transmembrane pressure and inversely proportional to the dispersed phase viscosity.
- *Surface wetting property.* The membrane pore wall with good wettability to the disperse phase allows a quick permeation of the phase in the pores and hence results in significant higher productivity (Piacentini et al. 2014).

Membrane Emulsification and Biotechnological Applications

Emma Piacentini

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Membrane emulsification is emerging as a unique tool for biotechnology applications. The advantages of membrane emulsification in biotechnology are related to the low shear forces on the functional and molecular properties of the biological compounds used and to the ability to tune the properties of emulsion droplets in terms of size and size distribution. Some examples include the use of membrane emulsification to assist enzymatic reaction. A simple emulsion with a heterogenized enzyme was produced using the lipase from *Candida rugosa* as model enzyme (Giorno et al. 2008) to catalyze the enantioselective hydrolysis of racemic naproxen methyl ester and produce (S)-naproxen (Fig. 1a). Lipase was distributed at the O/W interface, and the substrate of the reaction was dissolved in the dispersed phase. Emulsion droplet with controlled and uniform size provided a constant reaction interface. The enzyme optimal distribution at the interface of stable, uniform, and small droplets, produced in mild conditions able to prevent enzyme inactivation, allowed to obtain highly efficient enzymatic reaction. Microspheres with controlled size and size distribution were also prepared using membrane emulsification with different materials such as chitosan (Akamatsu et al. 2010) and polymethyl methacrylate (Omi et al. 1997), and they were used for enzyme immobilization.

O/w emulsions prepared by membrane emulsification were used in a multiphase reactor

Membrane Emulsification and Biotechnological Applications, Fig. 1 Membrane emulsification application in biotechnology

(Giorno et al. 2007). The emulsion has been first loaded within the membrane together with the enzyme, lipase from *Candida rugosa*, and then the emulsion + enzyme-loaded membrane has been placed between two separate phases, an organic phase containing the substrate and an aqueous phase where the product is extracted (Fig. 1b). The emulsion allowed to optimize the enantioselective activity of the immobilized enzyme and improved the mass transfer of the hydrophobic reagent through the membrane reaction system.

The concepts of membrane emulsification and biocatalytic membrane reactor have been integrated in a single operation unit to obtain bioconversion and simultaneous separation of reaction products (having different solubility and stability in water) (Fig. 1c). The microporous membrane

structure contained the immobilized enzyme, β -glucosidase, and the permeating water reaction phase was collected as droplets into the organic phase circulated along the lumen membrane surface. The oleuropein hydrolysis into glucose and isomer of oleuropein aglycon occurred within the membrane while the aglycon was simultaneously extracted in the organic phase (Mazzei et al. 2010).

The incorporation of highly specific, high-affinity binding proteins at emulsion interface was used to produce particles able to respond to specific physiological conditions (Fig. 2). A multiple emulsion containing a bio-receptor (Con A) that specifically recognizes and interacts with an artificial ligand (glucose) was manufactured by the membrane process and used as a model system (Piacentini et al. 2011). The inner W/O emulsion

Membrane Emulsification and Biotechnological Applications, Fig. 2 Sensing emulsion droplet production by membrane emulsification

and the multiple W/O/W emulsion were both prepared using membrane emulsification method in order to control emulsion droplet size and size distribution and to preserve the functional properties of the biological components used. The drug release was promoted by the change of the interfacial structure as consequence of the Con A-glucose interaction and occurred only when the effective stimulus concentration was used.

The size-controlled production methods by membrane operation open a new opportunity also in the cell-encapsulation technology (Fig. 1d). Some examples are related to the encapsulation of probiotic bacteria. *Lactobacillus casei* was encapsulated in Ca-alginate microcapsules (Song et al. 2003). Stability tests under simulate gastric conditions demonstrated that microencapsulation technology can protect viable cells from adverse gastrointestinal conditions. Bacterial cell coming from sludge samples from a batch reactor was encapsulated in uniformly sized agarose microcapsules by membrane process, and cell viability was preserved during the preparative process (Zhou et al. 2008).

Membrane Emulsification and Chemical Applications

María Matos, Gemma Gutiérrez and Carmen Pazos

Department of Chemical and Environmental Engineering, University of Oviedo, Oviedo, Spain

Membrane emulsification (ME) is a technique that can be employed to produce monodisperse

Membrane Emulsification and Chemical Applications,

Fig. 1 Schematic diagram of direct ME (i) and premix ME (ii)

emulsions with controlled droplet size, low energy consumption, and low shear stress. This technique was first developed in Japan in the 1990s using the Shirasu porous glass (SPG) membranes. These membranes were capable of producing droplets ranging from 0.3 to 40 μm in diameter (Nakashima et al. 1991). SPG membranes have been widely used for the production of emulsions and for conducting chemical reactions in emulsions. Both filtration membranes and hollow fiber modules are also used today for membrane emulsification (Nakashima et al. 1991; Vladisavljevic et al. 2002).

The droplet size and droplet size distribution influence the properties of an emulsion. In some applications, such as drug delivery systems, good control over droplet size and a narrow size distribution are required to ensure efficacious activity. Several factors can affect droplet size and the droplet size distribution in ME: composition of the emulsion, membrane characteristics, equipment, and operating parameters. There are two approaches to producing emulsions with membranes (see Fig. 1): (i) *direct ME*, in which the dispersed phase is pressed through the membrane into the continuous phase, and (ii) *premix ME*, where a coarse emulsion is forced through the membrane to reduce the size of the resulting droplets.

ME has been primarily used for emulsifying edible oils in the formulation of food products (e.g., the use of milk and egg yolk proteins as emulsifiers for preparing conventional O/W and W/O emulsions). ME is also widely used to prepare emulsions for the delivery of certain pharmaceuticals. Moreover, this technique has found many applications in chemical reactions involving emulsions. A typical example is emulsion polymerization, in which SPG membranes are used to produce monodisperse microspheres (Omi 1996). A monodisperse emulsion is obtained by forcing a dispersed phase containing a monomer into a continuous phase. If a porous structure is required, the dispersed phase may also contain an initiator and a cross-linking agent. The continuous phase retains the individuality of the dispersed phase droplets that will subsequently be converted to polymeric beads. Polymerization generally starts with a change in the operating conditions that facilitate reaction throughout the entire droplet or restrict it to the surface of the droplet. Different bead structures can be generated by various changes in process conditions. Drug delivery carriers and chromatography beads have been produced by this method (Zhou et al. 2007). Furthermore, similar reactions can also occur in a double emulsion (Ma et al. 2004).

Several polymerization reactions have been performed using SPG and ceramic membranes,

but metallic membranes have been also used in either batch, cross-flow, or rotating configurations. In addition organic polymers and silica particles can be generated for subsequent functionalization (Dragosavac et al. 2012).

SPG membranes have been also applied to printer toner preparation (Kiatkamjornwong et al. 2000), while hollow particles have been used to obtain plastic pigments for paint applications. These particles provide opacity and increase brightness (Vladislavjevic and Williams 2005).

Principles involved in generating ME have been also applied to extraction coupled with enzymatic reactions. These reactions can be performed using the enzyme to stabilize the emulsion droplets (Giorno et al. 2008) or using an immobilized form of the enzyme within the pores of the membrane. In the latter case, the reaction takes place within the membrane, while the product is collected as droplets on the continuous phase side (Giorno et al. 2007; Mazzei et al. 2010).

Membrane Emulsification and Food Applications

Emma Piacentini

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Emulsion production for encapsulation and delivery of functional compounds such as vitamins or probiotics or bioactive lipids is one of the emerging fields of membrane emulsification applied to food industry. Benefits of membrane emulsification for food applications include the low shear properties and the uniform size distribution that give high encapsulation efficiency and better control of the release properties. Vitamin B₁₂ was encapsulated in multiple solid-in-oil-in-water emulsion by premix membrane (Kukizaki 2009) and in solid lipid microcapsules by two-step membrane emulsification technique (Kukizaki and Goto 2007). Astaxanthin-loaded o/w emulsions were prepared by repeated premix membrane emulsification (Ribeiro et al. 2005). *Lactobacillus casei* cells have been encapsulated in uniform emulsions and microcapsules using the membrane emulsification technique (Song et al. 2003). The aim is to increase the activity and viability of the

microorganism to the stressful conditions of the stomach and the upper intestine by encapsulation. Fish oil microcapsules were produced from oil-in-water emulsions by premix membrane emulsification (Ramakrishnan et al. 2013). The combination of a low-energy emulsification technique (premix membrane emulsification) with spray drying allowed the production of fish oil microcapsules with an oil encapsulation efficiency of more than 50 %. Fish oil-in-water emulsions containing multilayered membranes produced by premix membrane emulsification demonstrated low in vitro digestibility (Gudipati et al. 2010). Results indicated that these emulsion systems could be used to modify the release of bioactive lipids in the gastrointestinal tract.

Milk components are often used in the preparation of food emulsions. The molecular or ultrastructural status of the milk components at the fat surface plays an important role in determining the functional properties of the food products. The advantage of membrane emulsification was pointed out to be the low shear forces on the physicochemical and molecular properties of the proteins. Oil-in-water emulsions with vegetal oil as dispersed phase and a milk proteins solution as continuous phase have been prepared using SPG (Scherze et al. 1999) and ceramic membranes (Joscelyne and Trägårdh 1999). Na-caseinate and b-lactoglobulin were used also in combination with the nonionic surfactant, Tween 20, in oil-in-water emulsions preparation by membrane emulsification (Christov et al. 2002).

Membrane emulsification has been tested also in the preparation of specific emulsion-based food product such as foamed food products like chocolate mousse, ice cream, or fresh cheese and low-fat product such as double emulsions and spread. Foamed food product where air is present as a component of several food products present (dispersed phase of bubbles or pores) was produced by membrane foaming. The method is based on pressing the dispersed phase as a form of gas through the membrane pores into the continuous phase while the continuous phase, containing whey proteins as surface-active substances, flowed along the membrane surface (Bals and Kulozik 2003a, b). Rotating membrane

emulsification was also used in the preparation of gas dispersion to improve the foam microstructure in terms of size and size distributions (Müller-Fischer et al. 2007). The Morinaga Milk Industry (Japan) developed and commercialized a low-fat spread using membrane technology (Okonogi et al. 1992). The volume fraction of dispersion water-phase reaches up to 75 % and the product is reported to be very stable, with suitable texture, and tasty. The potential for the easy scale-up is another attractive quality of membrane emulsification technology. Microencapsulation of vegetable oil droplets using cold water fish gelatine/gum arabic complex coacervation has been obtained at batch and large scale production using the stirred and the pulsed flow membrane emulsification (Piacentini et al. 2013).

Conventional oral drug administration methods, such as solutions, suspensions, tablets, and capsules, often do not provide protection from the acidic environment present in the stomach (Hillery et al. 2002) and do not provide a constant therapeutic blood concentration of the drug over time (Hoffman 2008). A re-administration of the drug is required, and the possibility of drug reaching the toxic levels is often high. Formulation of particles for the purpose of drug release systems has received increased interest over recent years (Freiberg and Zhu 2004). Encapsulating the drug (pharmaceutical) into particles of suitable size makes it possible to tailor the release, obtaining a site-specific release, prolonged action, and/or sustained release (Saltzman 2001).

In the physical sciences, a particle represents a small localized object to which can be ascribed several physical properties such as volume or mass. Particles may be solid, but they also may be liquid droplets dispersed in another immiscible

liquid or air. An emulsion is a dispersion of one liquid in another where the liquids are not miscible or are slightly soluble, and they play a valuable role in the production of the particle. Emulsion droplets are already particles, but, even more, the droplets after production may be converted into solid particles, suitable for the encapsulation within the core material (Hillery et al. 2002), by applying additional physical (fluidized bed coating, spray or freeze-drying, evaporation/solvent diffusion) or chemical (coacervation and interfacial polymerization) treatments.

The choice of the emulsification process is a key issue in the encapsulation as it influences directly the final size, and size distribution, of the solid particles. Some important challenges are required for the advancement of microencapsulation technologies in engineering microcapsules with improved functional and structured properties (Imbrogno et al. 2015):

- (i) Achieving precise control of particle size and size distribution in the emulsification step while maintaining the incorporation of biomolecules without affecting their activity, the distribution in the body, and the interaction with living cells as well as the drug release kinetics of the solid particles are greatly influenced by their size and uniformity (Huang et al. 2008).
- (ii) Maintaining the performance of a good emulsification step when the process is transferred from the laboratory scale to a larger throughput scale (Benita 2006; Dragosavac 2011).

Conventional emulsification processes such as high-shear rotor–stator mixers, high-pressure valve homogenizers, and ultrasonic and static mixers apply more energy than needed to disrupt the droplet, and the droplet breakup is mainly due to the turbulent eddies (Karbstein and Schubert 1995). In such devices, a premix is necessary, which is produced by gentle mixing, followed by homogenization which will lead to further reduction of the droplet size. In general, homogenization is an intense process: it introduces a large amount of energy into the premix emulsions to break the droplets into smaller ones (Dragosavac

2011). Conventional emulsification systems (Karbstein and Schubert 1995) are very convenient for production of droplets below 10 μm . For production of larger droplets (greater than 10 μm), low shear needs to be applied, but conventional homogenization in that case produces droplets with a wide size distribution. Such product is often unstable and has unsatisfactory properties.

By contrast, membrane emulsification (Nakashima et al. 1991) is a mild dispersion process to produce a monosized emulsion of one liquid phase in a second immiscible liquid phase using low energy per unit volume (Giorno et al. 2009; Vladisavljević and Williams 2005). The dispersed phase is pressed through the membrane into the continuous phase, and it is widely accepted that shear on the membrane surface needs to be applied in order to produce uniform droplets, and the growth and detachment of the droplets is a complex phenomenon dependent on the process conditions including the formulation of the dispersed and the continuous phases. Compared to conventional emulsification systems, membrane emulsification devices operate under constant temperature due to mild shear conditions, keeping heat and shear-sensitive ingredients intact and providing high encapsulation yields of multiple emulsions (Dragosavac 2011).

Numerous simple emulsions have been prepared using membrane emulsification w/o (Liu et al. 2008; Vladisavljević et al. 2002) and o/w (Vladisavljević and Williams 2010). The mild conditions of membrane emulsification are especially useful when the microencapsulation process involves the preparation of a multiple emulsions. Multiple emulsions are complex systems, termed “emulsions of emulsions” where droplets contain even smaller dispersed droplets within themselves (Garti 1997). Multiple emulsions have significant potential in many applications since they can serve as an entrapping reservoir for active ingredients that can be released from the inner phase to the outer phase by a controlled and a sustained mechanism (Garti 1997) suitable for pharmaceuticals. Most common multiple emulsions are

W/O/W emulsions (small water droplets dispersed within the larger oil droplet). This kind of emulsion is highly thermodynamically unstable, and emulsion breakdown can occur easily in the high shear stress conditions; therefore, the production by membrane emulsification is highly beneficial. W/O/W emulsions are produced by forcing the primary (W/O) emulsion through hydrophobic membrane into continuous phase. Lower shear (compared to conventional methods) is applied above the membrane surface to detach the droplets which are intact and have high encapsulation efficiency (Dragosavac 2011). Selecting the operating conditions (pore size and shear applied), it is possible to tune the final droplet size, and the process can be scaled up, keeping the performance demonstrated at the laboratory scale (Dragosavac 2011; Charcosset 2009). So far, membrane emulsification has been investigated for microencapsulation of water-soluble and lipophilic drugs within W/O/W emulsions such as ethanol–oil–water E/O/W and water–oil–water W/O/W (Vladisavljević and Williams 2005; Nakajima 2003) or within microspheres and capsules produced in most cases by coacervation, interfacial polymerization, and solvent evaporation (Huang et al. 2008; Charcosset 2012; Piacentini et al. 2013; Vladisavljević 2015).

Membrane Emulsification Applications

Emma Piacentini

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Membrane emulsification (ME) is used in the preparation of simple emulsions, multiple emulsions, foams, liposomes, coherent solids, and structured solid (Vladisavljević and Williams 2005; Table 1).

The range of application areas of ME includes (Giorno et al. 2009; Piacentini et al. 2010):

- Food

Emulsions are used in the preparation of dressings, artificial milks, cream liqueurs, margarines, and low-fat spreads. Sensitive food materials and flavors can be encapsulated to enhance the sensory perception. One example at industrial scale is the development and commercialization of a very low-fat spread using ME technology by Morinaga Milk Industry (Japan).

- Pharmaceutical

The drug-delivery system is one of the most attractive fields of ME. Emulsions and structured solidified particles have been prepared to transport and deliver anticancer drug, proteins, vitamins, and probiotics. $W_1/O/W_2$ emulsions have been prepared to transport and deliver anticancer drug for liver cancer treatment followed by clinical study.

- Cosmetic

Emulsion for the treatment, protection, care, and/or cleaning of the skin, mucous membranes and/or hair, and/or as makeup for the skin and/or mucous membranes have been prepared by ME.

- Other application

ME has been used in the preparation of emulsion fuel and photosensitive material.

Membrane Emulsification Applications, Table 1 Emulsions and particulate products produced by using membrane emulsification

Membrane emulsification applications		
Simple emulsions		Foam
Oil-in-water emulsion (O/W) 	Water-in-oil emulsion (O/W) 	
Multiple emulsions		Solid-in-oil-in-water dispersion (S/O/W)
Water-in-oil-in-water emulsion ($W_1/O/W_2$) 	Oil-in-water-in-oil emulsion ($O_1/W/O_2$) 	
Liposomes 	Coherent solids	
	Metal solder particle 	Solid lipid microspheres 
Structured solid		
Polimeric or gel microbeads 	Porous core-shell microcapsules 	Nonporous core-shell microcapsules 

The technology was demonstrated to be suitable in the construction of multiphase reaction systems using phase transfer (bio)catalysts and in combination with liquid–liquid extraction and enzymatic reaction to achieve simultaneous drop generation, chemical conversion, and interfacial mass transfer.

Coacervation; Core shell particles

Microencapsulation is described as a process of enclosing micron-sized particles of solids or droplets of liquids or gasses in an inert shell, which isolates and protects them from the external environment. Microcapsules (particles size in the range between 3 and 800 μm) consist of an inner core (in which the active molecule is entrapped) and a shell that covers and protects the core. Different types of molecules like active pharmaceutical compounds, proteins, peptides, volatile oils, food materials, pigments, dyes, monomers, catalysts, pesticides, etc. can be encapsulated with different types of shell materials that in most cases are natural or synthetic polymers.

The majority of the methods achieved for the preparation of microcapsules are based on the preparation of an emulsified system, in the first step, and the formation of the shell, in a second step. The shell formation can be obtained (i) by precipitation or gelation of a polymer around the core (coacervation or phase separation), (ii) by polymerization of monomers at the interface of two immiscible phases (interfacial

polymerization), and (iii) by evaporation of the solvent with the concomitant solidification of the polymeric shell around the core (solvent evaporation) (Jyothi et al. 2010).

The term phase separation describes a process in which a polymer solution separates in two immiscible phases (a polymer-rich phase and a polymer-poor phase) after a perturbation of the equilibrium of the system. The preparation of microcapsules with this method consists in three basic steps: (i) dispersion of the core material in a coating material of polymer solution (emulsification step), (ii) deposition of the coating material around dispersed solid particles or liquid droplets by inducing a separation of two immiscible phases, and (iii) hardening of the coating by cross-linking or thermal treatment.

Membrane emulsification can be used in the emulsification step to finely control the dispersion of the core material into the solution of coating material. This method basically consists in the permeation of the dispersed phase through a porous membrane to form droplets at the opening pore and the subsequent detachment from the membrane surface into the continuous phase. A distinguishing feature of membrane emulsification is the possibility to control the resulting droplet size by the optimization of membrane parameters (porosity, mean pore size, pore geometry, pore distance, wettability) and process parameters (wall shear stress, transmembrane pressure, membrane module configuration, temperature) and not by the generation of turbulent droplet breakup which characterizes conventional methods (stirring, sonication, homogenization). The controlled delivery of substances encapsulated in the core of microcapsules is highly dependent on the uniformity in shape and size of microcapsules. Membrane emulsification is an advantageous technique because of its effectiveness in producing narrow droplet size distributions at low-energy consumption and mild shear conditions, making it potentially suitable for the encapsulation of shear-sensitive compounds.

The formation of the shell material around the droplet of the core material can be induced by altering chemical or physical parameters on the basis of the nature of the polymer and the kind of

the polymeric system (see Table 1). From a thermodynamic point of view, a polymeric system can be distinguished in:

- *Binary system*, consisting of one polymer dissolved in a solvent
- *Ternary system*, consisting either of a single polymer in a binary solvent mixture or of two polymeric components in a single solvent

Salting out consists in the addition of concentrated electrolyte solution (such as sodium sulfate) to the polymer solution in order to induce a desolvation of the polymer that precipitates on the droplets of the core material (see Fig. 1). This kind of process is usually used to induce

the phase separation of the system containing gelatin in the aqueous phase.

The variation of pH can be applied either for binary system to induce the phase separation of polymer solution that has a water solubility pH dependent (such as chitosan; see Fig. 1) or for ternary system to induce the electrostatic interaction between polyelectrolytes with opposite charge (polyanion and polycation). The latter method is also known as “complex coacervation,” and gelatin/acacia (Arabic gum) is the most common system used for the preparation of microcapsules with this method. The interaction between the polymers can be induced by pH adjustment from a value at which the polymers carry the same charge to a value at which both polymers carry net opposite charge (see Fig. 2a).

A demixing of binary system can also be obtained by a reduction of the temperature of the system until a critical value at which the polymer solution is thermodynamically unstable and separates spontaneously in two liquid phases. The formation of a polymer film occurs through the growth of nuclei of concentrated polymer (see Fig. 1).

Besides temperature variation, a demixing of the polymer solution can also be achieved by the addition of a third component (nonsolvent) in

Membrane Emulsification in Phase Separation for Microcapsule Preparation, Table 1 Parameters to induce phase separation of polymer system

Polymer system	Phase separation process
Binary system	Salting out
	Variation of pH
	Variation of temperature
Ternary system	Induction of polymer-polymer interaction
	Addition of nonsolvent

Membrane Emulsification in Phase Separation for Microcapsule Preparation,

Fig. 1 Production of microcapsules by membrane emulsification and phase separation from binary system: salting-out, pH variation, temperature variation

Membrane Emulsification in Phase Separation for Microcapsule Preparation, Fig. 2 Production of microcapsules by membrane emulsification and phase

separation from ternary system: a) complex coacervation; b) addition of non-solvent

M

which the polymer is insoluble but the solvent is miscible. In this case, we have a ternary system of polymer, solvent, and nonsolvent, and the demixing in two liquid phases occurs when the nonsolvent overcomes a critical volume at which the system is thermodynamically unstable (see Fig. 2b). The formation of the polymer film around the core material is based also in this case on nucleation and growth of nuclei of polymer-concentrated droplets. This method can be used for the preparation of microcapsules with either an oil or aqueous core. In the first case, gelatin, polyvinyl alcohol, and ethyl cellulose dissolved in an aqueous phase are commonly used as coating material, and the addition of water-soluble solvent (such as ethanol, propanol, and acetone) induces the phase separation of the polymer solution. In the second case, hydrophobic polymers (such as biodegradable polyesters) are dissolved in solvent partially soluble in water (such as dichloromethane and ethylacetate) and are used as organic phase for the preparation of a

W/O/W double emulsion. The precipitation of the polymer occurred at the interface between the internal aqueous phase (core material) and the organic phase (coating material) after the addition of a nonsolvent (Arshady 1990, 1991; Gander et al. 2007; Olabis 2012).

An innovative method in which polymeric microsphere generation has been obtained by combining membrane emulsification process with phase separation induced in a single step is reported by Piacentini et al. (2013). In this case, a nonaqueous (O/O) emulsion is generated by injecting the polymeric solution through a microporous membrane into the nonaqueous continuous phase that works at the same time as phase separation inducer and allows the particle formation. In this case, droplet formation and solidification occur in a single step.

In Table 2 are reported some works in which microcapsules are prepared using membrane emulsification and phase separation.

Membrane emulsification (ME) process is governed by a significant number of variables that can be divided into membrane parameters (wettability, charge, porosity, pore size, pore morphology, and spatial arrangement of the pores),

Membrane Emulsification Modeling,

Fig. 1 Mean droplet size, d_d , in direct membrane emulsification (DME) (dashed lines) and premix membrane emulsification (PME) (solid lines) as a function of mean pore size, d_p , of the membrane and transmembrane flux, J : (1) d_d vs. J in shear-controlled DME; (2) d_d vs. J in DME, spontaneous drop detachment; (3) d_d vs. d_p in DME; (4) d_d vs. J in PME; and (5) d_d vs. d_p in PME. Reproduced with permission from Vladislavjević et al. (2015)

formulation parameters (viscosity of the dispersed and continuous phase, a nature of the surfactant used, surfactant concentration, etc.), and process parameters (shear generated on the membrane surface, transmembrane flux, etc.). The droplet size in direct membrane emulsification (DME) has been predicted analytically, using force and torque balance models (Timgren et al. 2010; De Luca et al. 2008; Williams et al. 1998), and computationally, using computational fluid dynamics (CFD) simulations (Kobayashi et al. 2004; Abrahamse et al. 2001) and the Surface Evolver software (Rayner et al. 2004).

Two mechanisms of drop detachment from the pores in DME have been identified: (a) shear-controlled detachment as a result of shear stress on the membrane surface and (b) spontaneous detachment driven by interfacial tension (Sugiura et al. 2002). In DME, a linear correlation between the mean droplet size and the mean pore size exists in dripping regime: $d_d = Kd_p$ (line 3 in Fig. 1), where K typically ranges between 2 and 6. In premix membrane emulsification (PME), the mean droplet size is a nonlinear function of the mean pore size (line 5 in Fig. 1): $d_d = K'(d_p)^n$, where $n < 1$. The d_d/d_p ratio decreases with increasing the mean pore size and the shear stress on the pore walls and ranges between 0.5 and 1.5.

In the shear-controlled DME process at $J \rightarrow 0$, the mean droplet size is determined by a balance between the shear force exerted on the liquid-liquid interface by the continuous phase and the capillary force. The mean drop size decreases with increasing shear stress on the membrane surface until it reaches a constant value at high shear stresses. The resultant drop size at $J > 0$ is greater than that at zero flux, because a droplet will continue to increase in size during the detachment period as a result of inflow of the dispersed phase via the droplet neck. The volume of the dispersed phase flowing into the droplet during the detachment phase increases with increasing the dispersed phase flow rate, and thus, the resultant drop size increases with increasing the transmembrane flux (line 1 in Fig. 1). At high transmembrane fluxes, the push-off force as a result of droplet-droplet interactions on the membrane surface should be added to the shear force in the shear balance model, causing a plateau region to occur on a d_d vs. J plot at high transmembrane fluxes (line 1 in Fig. 1) (Egidi et al. 2008). In the spontaneous droplet detachment process, the detachment period is very short, so the resultant drop size in dripping regime is virtually independent on the transmembrane flux (line 2 in Fig. 1).

In PME, the mean droplet size decreases with increasing the transmembrane flux (line 4 in Fig. 1) due to an increased shear stress within the pores at the higher flux. PME was modeled using the modified resistance-in-series model to account for droplet disruption (Vladisavljević et al. 2004) or energy density concept (Nazir et al. 2011).

Membrane emulsification (ME) is an emerging technology of droplet generation in which a dispersed phase or premix is forced through the pores of a microporous membrane into a continuous phase. In contrast to traditional approach of breaking and re-breaking droplets into successively smaller droplets until the desired droplet size range is achieved (Karbstein and Schubert 1995), ME creates each droplet directly at the final desired size without intermediate disruption and re-coalescence. This “made-to-measure” production approach requires less energy input and offers greater control over emulsion droplet size. ME is suitable when dealing with emulsions prone to disintegration, such as multiple emulsions (Surh et al. 2007; Dragosavac et al. 2012) and emulsions containing shear- and heat-sensitive ingredients. A shear rate on the membrane surface in direct ME is in the range of $(1\text{--}50) \times 10^3 \text{ s}^{-1}$, but droplets can be produced even in the absence of shear, while in high-pressure valve homogenizers, such as Microfluidizer[®], the shear rate can be as high as 10^7 s^{-1} . Energy input in conventional emulsification devices is spatially nonuniform leading to the production of polydispersed emulsions. In ME the shear is uniformly distributed over the membrane surface and precisely controlled by cross flow of the continuous phase, stirring rate or the rate of membrane oscillation or rotation. Cross-flow ME resembles microfluidic T junction; the main difference being that in cross-flow ME, the droplets are simultaneously formed from many different pores, and

Membrane Emulsification Principles, Fig. 1 (a) Oil droplet immersed in an aqueous phase and resting on a nonporous hydrophilic membrane surface; (b) Production of oil droplet by injecting oil phase through a hydrophilic pore into an aqueous phase; (c) Water droplet immersed in

an oil phase and resting on a nonporous hydrophobic membrane surface; (d) Production of water droplet by injecting aqueous phase through a hydrophobic pore into an oil phase

the cross-sectional area A_{ch} of the cross-flow channel is large compared to the cross-sectional area A_p of the pore ($A_{ch}/A_p > 1000$). Thus, the forming droplets are not confined by the walls of the cross-flow channel, and the drop generation mechanism differs to that in T junction (Vladislavjević et al. 2012).

The minimum transmembrane pressure for driving a pure oil phase through the pores with a diameter of d_p is the capillary pressure, P_{cap} , given by the Young-Laplace equation:

$$P_{cap} = \frac{4\gamma_{wo} \cos \theta}{d_p}$$

where γ_{wo} is the equilibrium interfacial tension between the water and oil phase and θ is the contact angle, i.e., the angle formed by a water phase at the three-phase boundary where the water phase, oil phase, and membrane intersect (Fig. 1a and c). A hydrophilic membrane ($\theta < 90^\circ$) is used in the production of O/W emulsion (Fig. 1b), and thus $P_{cap} > 0$ and $P_o > P_w$.

Membrane Emulsification Principles, Fig. 2 Droplet formation behavior in membrane emulsification: (a) critical pressure not exceeded (DME direct ME, PME premix ME); (b) optimal drop generation behavior (droplets do not interact with membrane surface or neighboring droplets);

(c) steric hindrance caused by small interpore distance compared to droplet diameter; (d) droplet coalescence on the membrane surface; (e) continuous outflow of the dispersed phase; (f) spreading of the dispersed phase on the membrane surface

A hydrophobic membrane ($\theta > 90^\circ$) is used in the production of W/O emulsion (Fig. 1d), and thus $P_{\text{cap}} < 0$ and $P_o < P_w$, i.e., the water phase pressure should be higher than the oil phase pressure by P_{cap} to drive the water phase through the membrane.

The capillary pressure in premix ME (PME) is given by (Park et al. 2001):

$$P_{\text{cap}} = \frac{\gamma_{wo} \left[2 + 2a^6 / \sqrt{2a^6 - 1} \times \arccos(1/a^3) - 4a^2 \right]}{a + \sqrt{a^2 - 1}}$$

where $a = d_1/d_p$ and d_1 is the mean droplet size in premix. The capillary pressure in PME is lower than that in DME, but for $d_1/d_p \gg 1$, the two capillary pressures are the same.

Different droplet formation behaviors in ME are shown in Fig. 2. If the transmembrane pressure is lower than P_{cap} , the dispersed phase will not pass through the pores in DME, and the membrane will reject the droplets in PME, which will lead to the separation of the premix into droplet-free continuous phase and concentrated emulsion (Koltuniewicz et al. 1995).

Uniform droplets are formed under optimum range of process parameters providing that the product formulation and membrane properties are appropriate (Fig. 2b). The problems associated with ME are steric hindrance between the droplets on the membrane surface as a result of insufficient distance between the pores (Fig. 2c), droplet coalescence due to poor stabilization of newly formed interface by surfactant molecules (Fig. 2d), continuous outflow of the dispersed phase (Fig. 2e), and droplet spreading on the membrane surface caused by the wetting the membrane surface by the dispersed phase (Fig. 2f).

Membrane Engineering

Enrico Drioli

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Department of Environmental and Chemical Engineering, University of Calabria, Rende, Italy

WCU Energy Engineering Department, Hanyang University, Seoul, S. Korea

Center of Excellence in Desalination Technology, King Abdulaziz University, Jeddah, Saudi Arabia

The way to satisfy the increasing demand for raw materials, energy, and products under the constraints imposed by the concept of sustainable development is a complex problem; possible solutions can be found through rational integration and implementation of new industrial, economic, environmental, and social strategies. A possible route to a more sustainable industrial growth is offered by the process intensification strategy, which is a design approach aimed at leading to concrete benefits in manufacturing and processing, substantially shrinking equipment size, boosting plant efficiency, saving energy, reducing capital costs, minimizing environmental impact, increasing safety, using remote control and automation, etc. (Drioli et al. 2011).

In this context, an interesting and important case is the continuous growth of modern membrane engineering, whose basic aspects satisfy the requirements of process intensification. In fact, it is well recognized that membrane processes have the potential to replace conventional energy-intensive separation techniques, such as distillation and evaporation, to accomplish the selective and efficient transport of specific components, to improve the performance of reactive processes, and, in the ultimate instance, to provide reliable options for sustainable industrial growth (Drioli and Giorno 2010).

Membrane operations, such as molecular separations, catalytic membrane reactors, membrane contactors, etc., with their intrinsic characteristics of efficiency and operational simplicity, compatibility between different membrane operations in integrated systems, low energy requirements, good stability under operative conditions, environmental compatibility, easy control and scale-up, and large flexibility, offer an interesting answer for advanced rationalization of a large variety of industrial processes.

In several different fields, these potentialities have already been realized. The growth in membrane installations for water treatment, for example, has been exponential over the past decade; this has resulted in decreased cost of desalination facilities, with the consequences that the cost of reclaimed water from membrane plants also has been reduced. Today, membrane technology is recognized as the most convenient approach in desalination, producing daily more water than thermal systems (Koltuniewicz and Drioli 2008; Macedonio et al. 2012; Strathmann et al. 2006).

Other areas, such as biochemical engineering, regenerative medicine, packaging, petrochemical industry, etc., have seen continuous innovations that, in the future, will lead to significant increased utilization of membrane operations in these sectors.

The term membrane engineering is becoming largely used and common for representing the engineering discipline covering all the membrane operations from pressure-driven membrane operations such as RO, NF, MF, UF, and gas separations to energy productions and membrane reactors, membrane distillation, and additional

types of membrane contactors. These membrane processes have all the possibility to replace conventional chemical unit operations.

The increased attention toward membrane engineering is also noticed by the establishment of a section on membrane engineering in the European Federation of Chemical Engineering (EFCE) founded in 2007, with the objective to promote strategic collaboration between experts in membrane engineering and related areas for addressing solutions and strategies interconnected to the membrane field.

Furthermore, a European Union-funded doctorate in the framework of the Erasmus Mundus program has been created to develop high-level education in the field of membrane engineering (Erasmus Mundus Doctorate in Membrane Engineering – EUDIME) with the aim to implement excellence, innovation, mobility, and multidisciplines related to membrane engineering.

Basic unit operations in process engineering such as distillation, crystallization, emulsification, condensers, etc., have here redesigned as membrane distillation (MD), membrane crystallization (MCR), membrane emulsifier (ME), membrane condenser (MC), etc. They are attracting growing attention. The development of integrated membrane operations in desalination, in fuel cells, in agro-food processes, etc., is becoming interesting industrial realities.

Membrane Extractor as a Configuration of Membrane Reactor

Juergen Caro

Institute of Physical Chemistry and
Electrochemistry, Leibniz University, Hannover,
Germany

Numerous practice-relevant reactions like dehydrogenations, esterifications, steam reforming Knoevenagel condensation, or thermal water splitting take place in industry under thermodynamic control. This means, there exists an equilibrium between products and educts due to $A + B \leftrightarrow C + D$ defined by $r_{RG} = -RT \ln K$ with r_{RG} as the Gibbs Energy (Free Enthalpy) of the reaction and K as the equilibrium constant. The “membrane extractor” concept is based on the selective in situ extraction of one or of both products C and/or D under equilibrium controlled reaction condition from the feed A, B . The main advantage of this concept is an enhancement of the conversion and increase of the yield (Dittmeyer and Caro 2008; Caro 2010). By the removal of C and/or D , sometimes also the selectivity is influenced.

The reaction must be sufficiently fast compared to the mass transport through the membrane, a feature called “kinetic compatibility.” Higher conversion – and thus yield – due to the beneficial effect of product removal may lead to savings on energy and raw materials, especially if the component removed through the membrane is pure enough for further applications. Historically, the selective hydrogen removal in alkane dehydrogenations to the corresponding olefins thus overriding the equilibrium constraint was the most studied membrane extractor case. The most prominent “membrane extractor reactors” studied at present are reformers for the production of fuel-cell-grade hydrogen from hydrocarbons or alcohols using Pd-based membranes. The removal of water through hydrophilic membranes in esterifications is another prominent example of “membrane extractor reactors.”

Besides conversion enhancement, also selectivity increase can take place in membrane extractors. For example, in Fischer–Tropsch synthesis, the removal of the by-product water has several advantages on the reactor performance like reduced catalyst deactivation or lowered kinetic inhibition.

Membrane Filtration in Biorefinery

Baoqiang Liao

Department of Chemical Engineering, Lakehead University, Thunder Bay, ON, Canada

Membrane filtration in biorefinery is the application of membrane separation technology in various stages of biorefining processes for process intensification, product recovery and purification, and bioenergy production. Membrane filtration is a separation technique that separates particles from a liquid by using a porous material. The liquid can pass through the pores of the membrane, while particles are retained by the membrane. A number of specific membrane processes are of particular value for biorefining and bioenergy production: microfiltration (MF) (pore size, 0.1–10 μm), ultrafiltration (UF) (pore size, 2–100 nm), nanofiltration (NF) (pore size,

1–2 nm), pervaporation (PV), membrane distillation (MD), and diafiltration (DF). The MF, UF, and NF processes use porous membranes and are driven by hydrostatic pressure; PV uses nonporous membranes and is driven by a chemical potential gradient, while MD uses porous hydrophobic membranes and is driven by a thermal gradient. DF uses porous membranes to remove salts or solvents from solutions based on molecular sizes. Among the various separation technologies used in biorefinery, membrane technologies provide excellent fractionation and separation capabilities, low chemical consumption, and reduced energy requirements.

In integrated forest biorefinery, MF and UF have been extensively studied for lignin and hemicellulose recovery and purification from kraft mill black liquor, spent sulfite liquor, and thermomechanical pulping's spent liquor (He et al. 2012). Furthermore, membrane filters are used in commercial production of lignins from kraft pulp black liquors (Kouisni and Paleologou 2010). In bioenergy production, membrane separations have been widely used in bioethanol production, including removal of fermentation inhibitors, enzyme recovery from the hydrolysis processes, membrane bioreactor for bioethanol production, and dehydration of bioethanol (Abels et al. 2013). In biogas production, anaerobic membrane bioreactors (AnMBR) have been successfully used for bioenergy recovery and water reuse from food processing wastewater (Christian et al. 2010) and alcohol stillage wastewater treatment (Grant et al. 2008). In bio-oil and biodiesel production, MF was examined for char particles from bio-oil, the liquid product from the pyrolysis of renewable biomass (Hoekstra et al. 2009); membrane reactor has been used for biodiesel production from waste vegetable oils and animal fats (He et al. 2012). Furthermore, membrane filtration has been used for separation and purification of biodiesel product by removing glycerol (Gomes et al. 2010). In algae production, membrane filtration has been studied for algal harvesting and dewatering to save energy (Bhave et al. 2012), purification of pigments from macroalgae (Denis et al. 2009), and recovery of triacylglycerols from wet microalgae for biodiesel production (Giorno

et al. 2013). It is anticipated that membrane filtration will play a significant role in biorefinery operations in the near future.

Membrane Fouling During Wine Processing

Martine Mietton-Peuchot

Vine and Wine Sciences Institute, Université de BORDEAUX, Villenave d'Ornon, France

Microfiltration was the first to be applied for wine clarification with membrane pore sizes from 0.2 to 1.2 μm . Nowadays, membranes are largely used in enology for must, lees, and wine in various applications. Membrane fouling results from complex interactions between macromolecular adsorption or deposition, internal fouling, and cake formation by the retained compounds. The respective impact of these different fouling mechanisms strongly depends on the composition of the fluid to be filtered, on the membrane characteristics, on the hydrodynamic conditions, as well as on the physical-chemical interactions between the fluid components and the membrane surface and between these components themselves. Membrane fouling may be induced by the adsorption of wine macromolecules and colloids to the membrane surface or within the membrane pores. Colloids in wine are pectic substances, yeast polysaccharides, proteins, and molecular aggregates resulting from the association of small solutes such as polyphenol aggregates. In wine, electrical charges play a secondary role in colloidal stability, while macromolecular colloids as polysaccharides have the most important role. In fact, macromolecular colloids are known as “protective colloids.” This protective effect is attributed to a coating of the colloid particles that prevents them from agglomerating. When eliminating polysaccharides by adding enzymes, the system becomes unstable and colloids tend to flocculate. Therefore, wine clarification becomes easier to process. Different membrane materials exhibit different levels of adsorption of typical foulants in wine such as polysaccharides. Larger amounts of polysaccharides are adsorbed to PES than to PP membrane. PES membrane presents hydrophilic character while PP membrane has hydrophobic character. Polysaccharide and tannin

Membrane Fouling

► Fouling

adsorption take part in irreversible fouling of membranes during the crossflow microfiltration of wine. This adsorption is dependent on the membrane surface properties, especially its surface free energy. Polysaccharide adsorption is governed by membrane polarity: it decreased as surface polarity increased due to hydrophilic repulsion between surface and the hydrophilic macromolecules. Mannoproteins play a crucial role in reducing the permeate fluxes. Mannoproteins have the most pronounced fouling effect among the polysaccharides in wine. Their impact on the flow is dependent on their concentration. Phenolic compounds have a much more important affinity for membranes than the polysaccharides, and there are both quantitative and qualitative differences between the different materials. There is a direct relationship between membrane polarity and the amount of adsorbed or deposited polyphenols. The adsorption of polyphenols seems to be governed by two mechanisms depending on membrane material: polar interactions and hydrogen bonds. Polyphenol adsorption increased as the polarity and the basic component of the membrane surface free energy increased. The adsorption of wine tannins on membrane surface occurs in static conditions. Under dynamic conditions, the rate of fouling and its type is strongly influenced by the transmembrane pressure. The increase in irreversible fouling can be explained by the transition between the states of dispersed molecules to aggregates. This fact is promoted by the increase of the transmembrane pressure which forces the molecules to be near the membrane surface and promotes membrane/tannins and tannins/tannins interactions. Few data exists on the effect of wine proteins on membrane fouling. This is due to their elimination before filtration by fining. The large particles and microorganisms in crude wine are generally only implied in reversible fouling, while the removal of these particles did not modify the irreversible fouling. Numerous parameters influence fouling of membranes (initial wine, pressure, crossflow velocity, membrane material, etc.). Due to the type of fouling, no clear critical flux for irreversibility can be really determined for wine microfiltration.

Membrane Micrograph

Carles Torras Font

Bioenergy and Biofuels, Catalonia Institute for Energy Research (IREC), Tarragona, Catalonia, Spain

Image is obtained from a membrane sample to acquire information regarding the morphology of the membrane (porous structure) (Torras et al. 2006). Nevertheless, it can also have other purposes, as characterized by fouling in the membrane (Saha et al. 2007). Typically, micrographs are two-dimensional images, although 3D reconstructions can be obtained by using advanced techniques (i.e., synchrotron) (Remigy et al. 2007). Equipment availability and characterization cost make 2D images to be the routine ones. Several apparatus can be used to obtain membrane micrographs: scanning electron microscopy, transmission electron microscopy, atomic force microscopy, etc. Due to typical sizes of membrane pores (from nanometers to hundreds of micrometers), scanning electron microscopy is, probably, the most versatile equipment. Nevertheless, if special attention is required in the nanometric range, atomic force microscopy may be the most suitable (phase and topographic images can be obtained) (Khulbe et al. 2008). Also, for large pore in sizes, optical microscopy can also be used. This last one is of special interest when used coupled with fluorescence, named confocal laser scanning microscopy (CLSM) (Ferrando et al. 2005). Nevertheless, for the last

Membrane Micrograph, Fig. 1 Polymeric membrane cross-sectional micrograph obtained by scanning electron microscopy

technique, the images can be named photographs since they are based on photons, while this last term cannot be used with electron microscopy, based on electron beams.

Two main types of 2D micrographs are obtained: surface and cross-sectional ones (Torras and Garcia-Valls 2004). Cross-sectional micrographs have the advantage to show the pore structure across all the membrane thickness (Fig. 1). In symmetric membranes (So et al. 1973), the pore size does not change in the mentioned direction, but it is usual that they do (asymmetric membranes), and in this last case, cross-sectional membranes are of special interest. Surface micrographs show the pore structure in a determined height of the membrane (considering height in the direction of the fluid flow, which is across the membrane). Usually, they correspond to the top and bottom side of the membrane. Surface micrographs let determine the regularity of the pores, check whether there is material deposited over the surface (a type of fouling), etc.

Membrane Microreactor

Arash Helmi

Department of Chemical Engineering and Chemistry, Chemical Process Intensification, Technische Universiteit Eindhoven, Eindhoven, The Netherlands

Today, several research groups are working on the development of novel apparatuses or methods that can dramatically decrease the equipment size to production capacity of various chemical processes. At the same time the objective is also to improve the energy efficiency of the plant with lower or no impact on the environment. This will finally lead to a cheaper and a more sustainable (more environmentally friendly) chemical process. This new trend in chemical process engineering is commonly named as “process intensification.” In general process intensification techniques can be categorized in two main streams: (1) process-intensifying equipment (e.g., static mixers, rotating devices, and microreactors) and (2) process-intensifying

methods (e.g., integration of reaction and separation in multifunctional reactor units such as in membrane reactors) (Stankiewicz and Moulijn 2000). Microreactors and membrane microreactors have the potential to be two key novel technologies for process intensification.

A microreactor is a device with size ranges of roughly 10–1000 μm (in length, width, height, and diameter) that is manufactured by means of precise engineering or microfabrication methods. Microreactors have several advantages and disadvantages in comparison with the conventional macroscale reactors. Microreactors are well known to outperform the conventional macroscale reactors in terms of heat and mass transfer characteristics (higher energy and material efficiencies). Also, microreactors are inherently safe to operate and normally have lower construction, operating, and maintenance costs in comparison with conventional macroscale reactors. At the same time microreactors have several disadvantages in compare with conventional devices. Clogging or fouling in microchannels, leakage between channels, and high fabrication cost of the reactor are the main drawbacks of going to microscale size range. Therefore, it is of paramount importance to select the most advantageous reactor type in each operating condition (Basile 2013).

A membrane reactor is a multifunctional device that integrates reaction and separation stages in one single unit and therefore enhances the efficiency of the process by reducing the number of steps. Membranes can be used to selectively remove components from the product stream to control the thermodynamic equilibrium of such a process (e.g., steam methane reforming). Also membranes can be applied to selectively add a reactant to the reaction zone to decrease the sharp increase in temperature at the presence of highly exothermic reaction. Therefore, integration of membranes to the reaction zone can enhance the efficiency of the process to higher degrees of process intensification.

The application of membranes to various chemical processes has been already investigated by several researchers (Basile 2013). Also microchannel reactors have been extensively

studied for the production of H_2 for fuel cell (via steam reforming, partial oxidation, water gas shift, and methanation reactions) (Hessel et al. 2009). Although a great interest has been paid on microreactors in the recent years, the application of membrane microreactors is still limited. Most of the literature on membrane reactors has been devoted on the production of H_2 using Pd-based membranes (Gallucci et al. 2013). More research needs to be devoted to the application and integration of membranes to microreactor devices.

Membrane Modification Using Dextran for Colloid Separation

H. Kawakita

Department of Applied Chemistry, Saga University, Saga, Japan

Membrane modification using dextran for colloid separation (also called dextran-produced membrane) is the most interesting technique for the separation. Dextranase (DSase), a kind of transferase, produces dextran from sucrose. The produced dextran forms the complex with the active site of DSase. Dextran is α -(1,6) glucose

Membrane Modification Using Dextran for Colloid Separation, Fig. 1 Pressure loss of membranes and the amount of dextran produced in permeating sucrose solution through DSase-immobilized membrane (Kawakita et al. 2007)

Membrane Modification Using Dextran for Colloid Separation, Fig. 2 Rejection percentage of latex bead by the amount of dextran produced (Kawakita et al. 2009)

polymer and has the flexible structure. Up to now, dextran has been applied for separation and incubation materials. Using this property of DSase, we modified the surface of membrane pores with dextran. DSase was immobilized within the membrane pores by passing a DSase solution through a Shirasu porous glass inorganic porous hollow fiber membrane. The interaction between DSase and membrane surface would be hydrophilic interaction. Via the interaction, the structure of DSase was not destroyed. Subsequently, a sucrose solution was passed through the DSase-immobilized membrane to generate dextran. In permeating sucrose solution, the produced dextran occupied the inner part of the membrane, because dextran is produced from the active site of DSase. The transmembrane pressure drop during solution permeation increased with increasing dextran production (Kawakita et al. 2007), as shown in Fig. 1. The porosity of the membrane filled with dextran was quantitatively determined from the pressure loss using the Kozeny-Carman equation. A colloidal particle suspension was passed through the dextran-modified membrane, showing rejection of the colloid particles by the dextran (Kawakita et al. 2007), as shown in Fig. 2. In methanol solution, dextran shrinks because the

hydrated water leaves from dextran. In permeating methanol/water solution through dextran-produced membrane, the pressure drop increased due to the shrinkage of dextran polymer. Next, the dynamic separation of colloidal particle was performed; colloidal particles were separated by the dynamically produced dextran. A colloidal particle suspension containing sucrose was also passed through a DSase-immobilized membrane, demonstrating that the colloidal particles were dynamically rejected during dextran generation (Kawakita et al. 2009). If DSase could be immobilized on polymeric materials, dextran with controllable hydrophilic characteristics could be generated by changing the density and the length of the chains.

Membrane Morphology

Lidietta Giorno

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Synonyms

Surface morphology

Surface membrane morphology studies provide atomic or nano-scale structure information about pore shape, pore size distribution, roughness, electrical properties, surface adhesion/membrane fouling behavior, and correlation between membrane characteristics and process behavior.

Analytical Imaging Techniques used for surface morphology study include

- Field Emission Scanning Electron Microscopy (FE-SEM)
- Focused Ion Beam – Scanning Electron Microscopy (FIB-SEM)
- High Resolution Optical Microscopy
- Scanning Transmission Electron Microscopy (STEM)
- Transmission Electron Microscopy (TEM)
- Ultra High Resolution-SEM (UHR-SEM)
- Atomic force microscopy (AFM)

These methods provide high-spatial-resolution images that show the relative surface morphology of membrane structure.

Atomic force microscopy has proved to be a powerful technique to study membrane morphology. It can magnify up to $\times 1,000,000$ in 3D view and can give important quantitative data analysis (including sizes, surface roughness, and area) about membrane surface in air or in liquid medium. Materials investigated using AFM include thick and thin film coating, ceramics, composites, glasses, synthetic and biological membranes, metals, polymers, and semiconductors (Khulbe et al. 2008; Hilal et al. 2012).

Although still controversial, there are some indications that correlate the process performance with the surface roughness. Irregularities on the membrane surface may affect the physicochemical properties of the membrane. The behavior strongly depends on the type of materials and method of membrane preparation. For example, it has been shown that for gas separation through poly(phenylene) oxide (PPO) membranes, permeability increases while selectivity decreases with an increase of surface roughness.

In pervaporation of water/ethanol mixtures through aromatic polyamide with acrylamide grafted by plasma polymerization, both separation factor and permeation rate increased linearly with roughness. In reverse osmosis membranes fouling seems to increase with surface roughness.

Membrane Preparation Techniques

Franco Tasselli

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Membrane technology is nowadays more and more employed in many separation processes such as water desalting and blood purification, to

mention two of the most known. Synthetic membranes can be prepared according to several techniques which allow to forge a material so as to give it the desired characteristics, the most important of which is the *morphology* (Mulder 1996; Baker 2004). In order to prepare membranes for a given separation, two aspects must be considered: the nature of the used material (organic or inorganic) and the morphology (dense or porous) of the membrane. In the table below, the most important techniques are reported together with salient features.

Sintering is a technique which allows to prepare membranes from powders of polymeric materials such as polyethylene (PE) and polypropylene (PP) or of inorganic materials such as stainless steel, metal oxides, graphite, or glass. This technique is based on the compression of the particles of the selected material and heating to a temperature below the *melting point* so as to induce a sticking of the particles. Between the stuck particles, *pores* are formed the size of which strictly depends on the particle size: the smaller the particle size, the smaller the pore size. The SEM micrograph of a stainless steel sintered membrane is shown in Table 1 (a). Sintered membranes are particularly suitable for applications in harsh conditions owing to the great resistance of the based materials in chemically aggressive environment or at high temperature. Polytetrafluoroethylene (PTFE), further to these outstanding properties, also exhibits high flexibility which makes it particularly suitable as membrane material.

Stretching technique is used to prepare porous membranes starting from extruded dense films of *semicrystalline* polymers such as PE, PP, and PTFE. Pore formation is obtained by stretching the film perpendicularly to the direction of extrusion until small ruptures occur in the structure of the dense film (SEM image (b) in Table 1). Pore size of membranes prepared by this technique (0.1–3 μm) makes them suitable for *microfiltration* applications. The *porosity* of the stretched membranes, given by the ratio of the void volume and the total volume of the membrane, may also reach 90 %.

Differently from all the others, membranes prepared by **track-etching** technique present uniform pores with cylindrical geometry (SEM image (c) in Table 1). The principle of the technique is the irradiation of a dense film of polymer, usually polyester or polycarbonate. The radiation crosses the film perpendicularly to the surface and damages polymer chains encountered along the path. A subsequent chemical treatment, typically with NaOH, removes the damaged material creating straight cylindrical pores. The number of pores and their size is determined by the exposure time to the radiation and to the etching treatment, respectively. A drawback of this technique is the rather low porosity of the membranes, ranging from 5 % to 10 %.

Phase inversion. This is the most versatile technique which allows the preparation of all kinds of membranes. Only polymeric membranes can be prepared, provided that the polymer is soluble in a solvent. According to this technique, a polymer dissolved in a solvent passes from the fluid state to the solid state under controlled conditions to give rise to the formation of membranes. The control of the operating conditions is crucial in order to prepare membranes with the desired morphology. The rate of removal of the solvent and the velocity of the phase separation are the most important steps which mainly determine the morphology of the membranes. With this technique it is possible to prepare membranes both in flat and in tubular conformation with morphology ranging from dense to microporous (SEM image (d) in Table 1).

Solution coatings. This technique allows the preparation of *composite membranes*, the use of which is desirable when the separation to be accomplished is controlled by the *diffusion* rather than by the size of the species to be separated. Membranes prepared with this technique are formed by two different materials the first of which is a thin dense film made of a selective polymer deposited on top of the second one which merely acts as a porous support. The SEM image (e) in Table 1 shows the cross section of a composite membrane. Such a conformation increases the transport rate through the membrane thanks to the thinness of the dense layer, while the

Membrane Pretreatment

Davide Mattia

Department of Chemical Engineering, University of Bath, Bath, UK

Membrane pretreatment refers to the series of source water conditioning processes in reverse osmosis desalination plants performed using membranes.

The polymeric thin film composite membranes used in reverse osmosis desalination plants require extensive pretreatment of the source water due to their structural limitations. Pretreatment steps include the removal of particulate, organic foulants, and, in some cases, chlorine. Conventional pretreatment technologies include granular media filtration using multiple layers of granular media (e.g., sand or anthracite) in single- or dual-stage configurations. These will not be covered further here. Membrane pretreatment is based on a combination of microfiltration (MF) and ultrafiltration (UF) and can be further classified according to the driving force, either pressure or vacuum if submerged.

Membrane pretreatment is becoming the dominant pretreatment method for RO plants with some of the largest installations in the world adopting it to replace conventional granular media (Gasia-Bruch et al. 2011). These include the Perth II plant (300,000 m³/day) in Australia

and the Shuwaikh plant (350,000 m³/day) in Kuwait (Gasia-Bruch et al. 2011).

The types of membranes and operating parameters for the pretreatment stage are linked to those of the RO membranes and the characteristics of the source water feed (pH, temperature, conductivity, turbidity, dissolved gases, particulates, etc.). Regarding the former, a common measure used in industry for the initial design of RO plants is the fouling index of RO membranes. This is based on a simple testing of the RO membrane using a feed containing a known amount of suspended or colloidal particles. The result is a numerical value that provides a relative estimate of fouling. The modified fouling index is a refinement of the previous one and is capable of discriminating the type of fouling mechanism occurring (e.g., pore blocking, cake filtration, etc.) (Schippers and Verdouw 1980). The initial design is then further optimized by coupling process parameters such as flux and transmembrane pressure between the pretreatment and the RO stages. Both dead-end and cross-flow are used in industry, with the former having lower footprint and energy costs but requiring intermittent operation to remove the accumulated solids and the latter capable of operating continuously but requiring a larger footprint due to lower packing density and higher energy costs due to the requirement of maintaining the tangential flow.

All membrane pretreatment installations have four basic modes of operation: filtration, backwash, cleaning, and integrity testing.

The flow direction is periodically reversed to remove accumulated solids on the feed side, a process known as backwash. Filtered water, concentrate, and air are all used, often in combination, with the objective of minimizing the backwash time while at the same time maximizing the removal of solids. Over time, membranes in the pretreatment stage require stronger chemical cleansing to remove biofilm and organic fouling. This process, often called maintenance wash, requires the removal of individual membranes from the line.

Backwash and maintenance wash do not remove completely membrane fouling, and a more extensive cleaning is required. Timing of this longer process varies with the feed quality as is generally triggered by a set reduction in the transmembrane pressure. Typical chemical cleansing includes recirculation of low pH solutions followed by high pH ones.

Polyamide RO membranes require the removal of all excess chlorine present in both maintenance wash and cleaning stages. Common methods include using a chlorine scavenger, such as sodium hydrogen sulfite, or sorbents such as activated carbon. The former method is more economic in terms of both capital and running costs and is generally preferred. Alternatively sodium hydroxide can be used to replace chlorine-based cleaning agents.

Integrity testing is performed periodically on pretreatment membranes to detect punctures or ruptures in the membranes. The most commonly used off-line test is the so-called pressure hold test, whereby air is forced through the membrane module at a certain pressure, the circuit closed, and loss over time is monitored. In-line testing is commonly based on monitoring changes in turbidity after each membrane module compared to the average turbidity of the whole train.

Membrane Reactor Equilibrium Conversion

Giuseppe Barbieri

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The equilibrium constant of any reaction is function of temperature only. The equilibrium of a conventional/traditional reacting system is function only of the thermodynamic variables (temperature, pressure, and mixture composition). It is independent from the reactor model (continuous stirred tank reactor, plug flow reactor, batch reactor, etc.), fluid dynamics (mixing, diffusion, etc.), heat exchange (isothermal, adiabatic, or no-isothermal reactor), reactor size, etc. since the equilibrium is reached when variation in temperature, pressure, and composition is no longer present in the chemical system.

This condition is mathematically expressed by the following equations set valid for a reacting closed (no mass transfer with the environment) system consisting of N reactions.

$$Kp_j = \prod_{i=1}^{N^{\text{Gas}}} [P^{\text{Reaction}} x_i(X_1, X_2, \dots, X_N)]^{v_{ij}} \quad (1)$$

$$j = 1, \dots, N^{\text{Reaction}}$$

The formulation in terms of Kp constants enables for the evaluation of reaction conversion and hence the equilibrium composition of the reacting system kept under a set reaction pressure. As well known, the equilibrium expresses the highest limit for reaction conversion, and it will be here indicated as **TREC** (Traditional Reactor Equilibrium Conversion).

The conversion of a real chemical reactor (of finite size) depends on several factors, e.g., reactor model, feed flow rate, residence time, and heat transfer with the environment in addition to the variables before indicated. Thus, its conversion is always lower than the equilibrium one.

A membrane reactor (MR) has, in addition to the traditional reactor, another chamber/volume: the one named permeate. Therefore, it consists of two (reaction and permeation) volumes separated by a selective membrane. One can image each chamber is provided with a piston moving without friction, for keeping a constant pressure; consequently, the reaction and permeation volumes change according to the pistons movement. In addition, the reaction pressure can be different from the permeate pressure. During the reaction, the chamber volumes change for achieving the chemical and permeating equilibria. As the reactive equilibrium, the permeative one has a dynamic character such as the reactive one; this means molecules (if any) permeating the

membrane from reaction side to permeate side are equal in number to the molecules permeating in the opposite direction.

Temperature, pressure, and composition of the permeate can be different from those of reaction volume. These variables have also to be taken into account for evaluating the equilibrium of an MR. Nevertheless, another constrain is required for the equilibrium of an MR in addition to the one defined by Eq. 1 for the traditional reactor. This is the permeation equilibrium expressed as the equality of the chemical potentials (e.g., partial pressures for a gas phase reaction) (Barbieri et al. 2001, 2005; Marigliano et al. 2003) on both membrane sides of any permeable species Eq. 2.

$$\begin{aligned} \text{ChemicalPotential}_i^{\text{Equilibrium}} &= \text{ChemicalPotential}_i^{\text{Reaction}} = \text{ChemicalPotential}_i^{\text{Permeation}} \\ \text{Pressure}_i^{\text{Equilibrium}} &= \text{Pressure}_i^{\text{Reaction}} = \text{Pressure}_i^{\text{Permeation}} \end{aligned} \quad (2)$$

$\forall$ permeable species

This condition is independent from the membrane type and permeation rate. As chemical equilibrium in a conventional reactor, and in an MR as well, is independent from the reaction path, similarly the MR equilibrium is independent from permeation rate.

The hydrogen permeates Pd-based membranes following the Sieverts law. Even though, the membrane characteristics (e.g., Pd, Pd-Ag, thickness, etc.) influence the permeation rate and hence the time necessary to reach the equilibrium, the value of these parameters does not affect the MR equilibrium.

The equilibrium depends on the extraction capacity of the membrane system which is a function of the temperature, pressure, and composition of the MR permeate volume that directly gives the condition of Eq. 2.

The **MREC** (Membrane Reactor Equilibrium Conversion) can be easily calculated using the constrains of Eqs. 1 and 2. MREC can be also calculated using the thermodynamics table for the reaction(s) adding to it the terms related to the permeative equilibrium.

Table 1 reports the thermodynamics table for calculating the equilibrium conversion of the water gas shift reaction in a Pd-based MR, all the figures are in moles. The procedure for calculating the number of moles at the equilibrium is the one known since long time from chemistry as the fourth row “reactive equilibrium state” of Table 1 shows. In fact, in absence of a membrane this conversion is the one of a traditional reactor and here is identified as TREC. The presence of a selective membrane contributes to product (hydrogen) removal and hence to increase the equilibrium conversion because of the mass law effect or the Le Châtelier–Braun principle. Therefore, the equilibrium conversion of a reactor conversion (here named MREC) is always higher than TREC. MREC is equal to TREC in absence of any permeation.

Membrane Reactor Equilibrium Conversion, Table 1 Thermodynamics table for water gas shift reaction ($\text{CO} + \text{H}_2\text{O} = \text{CO}_2 + \text{H}_2$) in an MR. Both reaction and permeating equilibrium are taken into account

Reaction	CO	H ₂ O	CO ₂	H ₂
Initial state	n_0	$m n_0$	$m_1 n_0$	$m_2 n_0$
Reaction conversion	$-x n_0$	$-x n_0$	$x n_0$	$x n_0$
Reactive equilibrium state	$n_0 (1-x)$	$n_0 (m-x)$	$n_0 (m_1 + x)$	$n_0 (m_2 + x)$
Permeation	—	—	—	$-z [n_0 (m_2 + x)]$
Reactive and permeative equilibrium state	$n_0 (1-x)$	$n_0 (m-x)$	$n_0 (m_1 + x)$	$n_0 [(m_2 + x) (1-z)]$
Total mole number	$n_0 [1 + m + m_1 + m_2 - z (m_2 + x)]$			

Where, $m > =x$; $x = \text{MREC}$; z permeate hydrogen fraction
 m , m_1 , and m_2 are the feed molar ratio with respect to CO of H₂O, CO₂, and H₂, respectively

The fifth row includes the term (z) for hydrogen permeation through a Pd-based membrane, whereas the sixth row reports the moles present in the reaction volume under the reactive and permeative equilibrium condition.

The total mole number in an MR owing to permeation is lowered by the reducing term $\{-z [n_0 (m_2 + x)]\}$ with respect to traditional reactor.

The equilibrium constant of the reaction (reactive constrain, see Eq. 1) for WGS reaction considering the reactive and permeative equilibrium terms can be expressed as

$$K_P = \frac{(m_1 + x)[(m_2 + x)(1 - z)]}{(1 - x)(m - x)}$$

The other, permeative constrain Eq. 2 for the hydrogen, the only permeating species is

$$P_{H_2}^{\text{Equilibrium}} = \frac{n_0 [(m_2 + x)(1 - z)]}{n_0 [1 + m + m_1 + m_2 - z(m_2 + x)]} P^{\text{Reaction}}$$

CO conversion and the hydrogen fraction permeate the membrane are calculated resolving this set of two equation in two unknowns: the conversion (MREC) and the hydrogen permeated the membrane.

Another example of using thermodynamics table is reported for the n-butane dehydroisomerization (Al-Megren et al. 2013). This reaction (reaction 3) involves the dehydrogenation of n-butane (reaction 1) and successive isomerization to isobutene (reaction 2). The main products measured were normal butenes, isobutane, and isobutene.

From the thermodynamics table (Table 2), after some algebra, the equilibrium constants for reaction 1 and reaction 2 and the permeation equilibrium condition are:

$$K_{P1} = \frac{x^2(1-z)(1-w)}{(1+x-xz)(1-x)} P^{\text{Reaction side}}$$

$$K_{P2} = \frac{w}{(1-w)}$$

$$P_{\text{hydrogen}}^{\text{Equilibrium}} = P^{\text{Reaction side}} \frac{x(1-z)}{(1+x-xz)}$$

This is a set of three equation in three unknowns that resolved for x , w , and z gives the conversion

Membrane Reactor Equilibrium Conversion, Table 2 Number of moles determination at reactive and permeative equilibrium in a membrane reactor

Moles	n-butane	n-butene	Isobutene	Hydrogen
Initial state	n_0	—	—	—
Reactive state of reaction 1	— $n_0 x$	$n_0 x$	—	$n_0 x$
Reactive state of reaction 2		— $n_0 x w$	$n_0 x w$	
Permeation state	—	—	—	— $n_0 x z$
Permeative and reactive equilibrium state	$n_0 (1 - x)$	$n_0 x (1 - w)$	$n_0 x w$	$n_0 x (1 - z)$
Total number of moles				$n_0 (1 + x - xz)$

Where, x = MREC for [reaction 1](#), w = MREC for [reaction 2](#), z permeate hydrogen fraction
The initial concentration of n-butene, isobutene, and hydrogen was chosen as zero

values (MRECs) of the [reaction 1](#) and [reaction 2](#) and the permeate hydrogen fraction.

important role in determining how the membrane surface will interact with its environment. For example, surface roughness is important in evaluating the performance of a membrane as it may influence the transmembrane transport and fouling potential of the membrane (Hobbs et al. 2006). The surface roughness may also correlate with other material characteristics such as the pore-size distribution and molecular weight cutoff (Bowen and Doneva 2000). Membrane roughness is usually quantified by one or more of a range of parameters. The most common parameters used are:

- (i) Peak-to-valley roughness
The peak-to-valley roughness describes the maximum observed range in a sample area and is given by the distance between the highest peak ($Z_{\max}$) and the lowest valley ($Z_{\min}$) on the measured surface, where Z indicates the vertical height of the surface:

$$R_{pv} = Z_{\max} - Z_{\min}$$

- (ii) Average roughness
The average roughness (R_a) is the most widely used because it is a simple parameter to obtain when compared to others. The average roughness is calculated using

$$R_a = \sum_{n=1}^N \frac{|Z_n - \bar{Z}|}{N}$$

where Z_n is the height at sample point n , $\bar{Z}$ is the height of the center plane, and N is the total number of points in the sample area.

Membrane Roughness

Paul Melvyn Williams
College of Engineering, Swansea University,
Swansea, UK

Membrane Roughness: Surface roughness is a measure of the texture of a surface. For membranes, the roughness may be defined as the deviation of the actual membrane surface topography from an ideal atomically smooth surface. Roughness plays an

(iii) Root-mean-squared roughness.

The root-mean-squared roughness (R_{RMS}) is a statistical measure used in many different fields. The R_{RMS} value is given by the standard deviation of the Z values for the sample area:

$$R_{RMS} = \sqrt{\sum_{n=1}^N \frac{(Z_n - \bar{Z})^2}{N}}$$

The RMS roughness of a surface is similar to the average roughness, with the only difference being in the use of the mean-squared absolute values of the surface roughness profile. As the RMS roughness contains square terms, large deviations from the average height are weighted more heavily than for the mean roughness.

Experimental determination of the membrane surface roughness is almost always conducted using atomic force microscopy (AFM). However, there is some difficulty when comparing results reported in literature due to the variation in the methods applied and the sample areas examined (Boussu et al. 2005).

Membrane Rugosity

Paul Melvyn Williams
College of Engineering, Swansea University,
Swansea, UK

Membrane Rugosity: Membrane rugosity is a measure of small-scale variations or amplitude in

the height of a surface. The rugosity (or roughness factor) of a surface, f_r , is calculated using the ratio (IUPAC et al. 1997):

$$f_r = \frac{A_r}{A_g}$$

where A_r is the real (actual) surface area and A_g is the geometric surface area.

Membrane rugosity is synonymous with membrane roughness (see entry on ► [membrane roughness](#)).

Membrane Separation of Inorganic Acids

B. S. Ooi
School of Chemical Engineering, Universiti Sains
Malaysia, Nibong Tebal, Pulau Pinang, Malaysia

Membrane technology plays a particular role in acid recovery through their specific separation mechanisms. Membrane processes in mode of electrodialysis, diffusion dialysis, nanofiltration/reverse osmosis, and membrane distillation system are commonly employed. Their role as clean technologies reuses acids as valuable materials and therefore contributes to reduction of the environmental load.

Electrodialysis (ED) has been used for the recovery and recycling of dilute waste acid. Electrodialysis is used to transport salt from the diluate to the concentrate by applying an electric current. The ions are transported through semipermeable membrane, under the influence of an electric potential. Cation-selective membranes are negatively charged matter, which rejects negatively charged ions and allows positively charged ions

Membrane Separation of Inorganic Acids, Fig. 1 (a) Bipolar electrodialysis, (b) chemo-dialysis, (c) reverse osmosis/nanofiltration, (d) membrane distillation

(Na^+ , H^+) to flow through, whereas anion-selective membranes will allow negatively charged ions (Cl^- , OH^-) to permeate. The separation mechanism of ED is shown in Fig. 1a. ED was able to concentrate the acid by a factor of 2–3 (up to concentration of 1.0 M). Available ion exchange membranes used in electrodialysis applications include Neosepta[®], Selemiom[®], Aciplex[®], Nafion[®], and Ionac[®]. A short-term test using membrane Raipore 6030 from Pall shows that the energy requirement can be as low as $1.41 \text{ kW.h.kg}^{-1}$ and maximum achievable of 80 % nitric acid in anolyte (Ponce-de-León and Field 2000).

A process of chemo-dialysis (CD) using a chemically active membrane material such as poly(benzimidazole) has been proposed for the transport of inorganic acids. Acids are transported across the membrane by concentration gradient as the driving force. The transported acid molecules are stripped away from the permeate side by a suitable stripping agent. These membranes show appreciable transport rates for H_2SO_4 , HCl , and HNO_3 with the fluxes for different acids varied from 15 to $140 \text{ g/m}^2 \text{ h}$ under different operating conditions. CD with high selectivity towards noncharged solute eliminated the requirement of acid neutralization, thus this process is

economically attractive. The schematic diagram of CD is shown in Fig. 1b.

The coupling reverse osmosis (RO) and nanofiltration (NF) are effective methods that could replace the conventional extraction method for acid recovery. Both RO and NF are pressure driven process which allows the uncharged water molecules to pass through but retain the charged acid molecules through size and charge exclusion (Fig. 1c). Stability of the membrane under such a low pH is always a concerning issue.

Recently, membrane distillation (MD) was suggested for the regeneration of volatile inorganic acids from the metal pickling solutions using hydrophobic porous and nonporous asymmetric membranes. Membrane distillation is a thermally driven separation process in which separation is enabled due to phase change or vapor pressure difference between feed and permeate (Fig. 1d). It was shown that the concentrating of volatile inorganic acids in the feed using a porous tetrafluoroethylene/vinylidene fluoride copolymer (MFF-2) membrane is effective up to 1.0 N concentration (Elkina et al. 2013).

Membrane Stripping

Gerardo León
Departamento de Ingeniería Química y
Ambiental, Universidad Politécnica de Cartagena,
Cartagena, Spain

Membrane stripping (synonym: membrane releasing) is a process to release in the product phase of a liquid membrane a target specie, which has been

transported through the membrane phase alone or complexed with a carrier, by the reaction, in the membrane phase/product phase interface, with a chemical specie or stripping agent added to the product phase. A liquid membrane is a system that involves a liquid (membrane phase), immiscible with the source solution (feed phase) and with the receiving solution (product phase), which serves as a semipermeable barrier between those two phases. The target specie can be transported from the feed to the product phase by dissolving in the membrane phase and diffusing to the product phase due to the concentration gradient between these two phases. It can also be done by forming (in the interface feed phase/membrane phase) with a carrier compound, added to the membrane phase, a reversible complex which is transported through the membrane phase due to its concentration gradient and broken (in the membrane phase/product phase interface), liberating the target specie in the product phase. In both cases, the process ends when the concentration of the target specie equalizes on both sides of the membrane phase. In order to improve the effectiveness of the liquid membrane separation processes, by maximizing both the extraction velocity (flux through the membrane phase) and the reception capacity of the diffusing specie in the product phase, a stripping agent is added to the product phase to release the target specie in that phase. The membrane stripping process occurs in the membrane phase/product phase interface in two ways. The first is by direct reaction of the stripping agent with the target specie; this gives rise to a membrane insoluble product that prevents it from diffusing back through the membrane (type I facilitation) (Fig. 1a). The other way is by reaction of the stripping agent with complex carrier-target specie, breaking that complex, removing the target specie from that complex, releasing it in the product phase, by formation (Fig. 1b) or not (Fig. 1c, d), with the stripping agent, the insoluble compound in the membrane phase, and regenerating the carrier, which initiates a new transportation cycle (facilitated transport type II) (Chakraborty et al. 2010; Vitt et al. 2010).

When the reaction between the diffusing specie and the stripping agent leads to a membrane

Membrane Stripping, Fig. 1 Membrane stripping of (a) an organic base by HCl; (b) an organic acid/carrier complex by NaOH; (c) a metallic ion/carrier complex by protons; (d) an amino acid/carrier complex by chloride ion

insoluble product, the driving force for the transport is generated by the concentration gradient of the target specie across the membrane phase due to the reduction to zero of its concentration in the product phase. When the reaction between the stripping agent and the target specie-carrier releases the target specie in its original form, the driving force for the transport of the target specie is maintained by a concentration gradient of a second specie transported in the opposite direction. Different types of membrane stripping processes can be used, but they should all be quantitative and very fast. The choice of a specific membrane stripping process should be determined by the nature of the target specie to be removed and recovered and by the nature of the carrier, if carrier-mediated transport is used. In this case, the selection of the carrier/stripping agent system is based on thermodynamic and kinetic considerations (Gu et al. 1992). Thermodynamically, the selected carrier should favor the formation of its complex with the target specie in the feed/membrane interface and its rupture in the membrane/product interface. Kinetically, the

selected carrier/stripping agent system should exhibit fast reactions for both extraction and stripping processes.

Membrane Swelling

Annarosa Gugliuzza

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Slow diffusion of solvents into polymer chains causes a swelling phenomenon and leads to a swollen polymeric membrane (Fig. 1). In this case, an expansion of the polymer network is promoted because polymer-polymer interactions are over polymer-solvent forces and a complete dissolution of the membrane is prevented (Billmeyer 1984).

Different degrees of swelling can be achieved depending on cross-linking, crystallinity, as well as intermolecular forces involved. The choice of the materials and their combination can direct the swelling events and make the membrane performance addressable at macroscopic level (Barton 1983). Membrane swelling over an area of 1 mm² is indicated as a bulk swelling, while small changes in dimension are classified as a microscopic swelling and are detectable by small-angle X-ray scattering (SAXS).

The macroscopic swelling is usually calculated by gravimetric measurements according to this relation:

$$G(\cdot/\cdot) = \frac{m - m_0}{m_0} \cdot 100 \quad (1)$$

where G is the percentage of swelling, m the mass of the wet membrane, and m_0 the mass of the dry membrane. The gravimetric method is, however, somewhat limited and inadequate when slow

anisotropic swelling equilibrium is reached or swelling kinetics need to be detected in real-time. In this case, in situ detection of the dimensional membrane is requested when moving from dry to wet state (Izak et al. 2007).

Robust network architectures of swelled membranes with high surface-to-volume ratio are generated when swelling takes place along three directions, x , y , and z . This physical expansion can be estimated by using the following relation:

$$\tau(\cdot/\cdot) = \frac{l - l_0}{l_0} \cdot 100 \quad (2)$$

where τ is the percentage of the membrane dimension; l the dimension of the wet membrane along the x , y , or z axis; and l_0 the dimension of dry membrane along the considered axis (Gugliuzza and Drioli 2007). The swelling can be isotropic when the expansion is equal in all directions, whereas differential dimensional changes in the plane (x , y) or along the vertical axis (z) to the plane lead to an anisotropic swelling (Fig. 2).

Reversible swelling is called as a deswelling. The cycle of swelling-deswelling is a mechanical work, which is often used in actuation and biosensing and drug delivery. In this case, switching swollen polymers are indicated as smart gels (Diaconu et al. 2012).

In dense membranes, a large sorption of molecules can induce swelling of the matrix leading to an increase in free volume. Higher mobility of the polymer chains reduces the discriminating power of the membrane, causing plasticization when macroscopic segmental motion occurs. In porous membranes, macroscopic swelling could lead to

M

Membrane Swelling,

Fig. 1 Reversible expansion and shrinking of polymer chains after solvent adsorption/desorption

Membrane Swelling, Fig. 2 Isotropic and anisotropic expansion of 3D polymeric networks along three axes (x , y , and z)

an increase in the polymer volume with closure of porous structures and subsequent abatement of the flux.

Membrane Topography

Paul Melvyn Williams
College of Engineering, Swansea University,
Swansea, UK

Membrane topography: At the nanoscale membranes are not flat surfaces. Membrane topography is concerned with the study of the membrane surface shape and features. In a broader sense, membrane topography is concerned with detail in general about membrane surfaces. Some of the more popular surface characterization techniques for membrane topography include

scanning electron microscopy (SEM) and atomic force microscopy (AFM). Each of these tools is capable of providing atomic-level quantitative analyses of the morphological characteristics of membrane surfaces. Using these tools, it is possible to characterize membrane properties like surface roughness, porosity, and pore size distribution (Bowen and Hilal 2009; Barbosa and Silva 2012) (Fig. 1).

Membrane Use in Biodiesel Production from Microalgae

Baoqiang Liao

Department of Chemical Engineering, Lakehead University, Thunder Bay, ON, Canada

In biodiesel production from microalgae, membrane separation can play an important role in process intensification and product purification. Membrane technology can be easily integrated into various steps of biodiesel production: harvesting and dewatering of microalgae and purification of triacylglycerols from wet microalgae for biodiesel production.

Algal biomass harvesting refers to the process of concentrating a diluted microalgae broth (<1 wt%) to a slurry or solid paste containing 5–25 % wt, or more, total suspended solids (Grimaa et al. 2003). Algal biomass harvesting is a significant challenge in microalgae production, due to the unique physical properties of microalgae, including the small size (3–30 μm) of microalgae cells and a density comparable to water. The cost for algal biomass harvesting accounts for 20–30 % of the operational cost of microalgae production (Grimaa et al. 2003). Among various techniques (gravity sedimentation, centrifugation, filtration, flocculation, flotation, electron-coagulation) used for microalgae harvesting, membrane filtration has many advantages, including the high separation efficiency, low energy cost, operational simplicity, and reduced chemical addition. In microalgae harvesting, both pressure and vacuum filter are promising filtration technologies. For relatively

larger microalgae cells, such as *Coelastrum proboscideum* and *Spirulina platensis*, both pressure and vacuum filter can achieve excellent filtration performance (Mohn 1980). In a pressure filter, a concentration factor of 245 was achieved in batch filtration for microalgae *C. proboscideum* to produce a slurry with a total suspended solids of 27 wt% (Mohn 1980). Furthermore, two recent studies indicate that a concentration factor of 75–150 was obtained for to produce a cake of >150 g/L solids (Bhave et al. 2012; Zhang et al. 2010). A reduction of 99 % in volume and 90–99 % removal of water were achieved in dewatering (Bhave et al. 2012). The permeate was free of solids. However, for microalgae with small sizes, membrane filtration may be a challenge, due to biofouling of microalgae on membrane surface. At present, large-scale application of membrane technology for producing algal biomass is not common, but small aquaculture farms do frequently use membrane technology for recovering algal cells for feeding shellfish larvae (Borowitzka 1997). With the progress of membrane technology, it is anticipated that membrane filtration will provide a stable, reliable, efficient, and cost-effective dewatering option for large-scale processing of microalgal biomass for the production of biofuel in the near future (Bhave et al. 2012).

In biodiesel production from microalgae, in addition to microalgae harvest and dewatering from diluted culture media, product recovery, such as triacylglycerols (TAG), from wet microalgae is another key aspect, because of energy saving gained from avoiding biomass drying (Giorno et al. 2013). The study of a single unit membrane filtration for simultaneous microalgae (*Nannochloropsis*) harvesting and TAG recovery showed that both regenerated cellulose (RC) membranes with nominal molecular weight cutoff of 100 and 30 kDa allowed to recover permeate with high content of TGA, but the 30 kDa RC membrane gave a higher purity of TGA with less other coproducts (Giorno et al. 2013). A stable of membrane filtration flux of 20–22 L/m².h was observed for both RC membranes. It appears that the combination of a membrane filtration process with an ultrasonic-assisted

cell breakage is a promising technology for oil recovery from wet microalgae cells.

Membrane Wettability

Annarosa Gugliuzza
Institute on Membrane Technology, National
Research Council of Italy, ITM-CNR, Rende,
Italy

The concept of wettability (S) is referred to the ability of a liquid to wet a surface (Hsu et al. 2011). The degree of wettability, also known as a wetting or spreading, is controlled by interfacial forces established between a liquid (L), solid (S), and vapor (V) phase at the minimum equilibrium distance. These interaction types are usually expressed as surface tensions (γ) and can be correlated to the wettability coefficient by a mathematical equation:

$$S = \gamma_{SV} - (\gamma_{SL} + \gamma_{LV}) \quad (1)$$

The surface tension, expressed as a force per unit length [N/m] or energy per unit surface area [J/m²], is a direct measurement of the cohesive energy required for minimizing the free surface area at the interface, where the number of similar species is more restricted than bulk and attractive forces are unequal and unbalanced in all directions (Fig. 1).

This parameter and related polar and nonpolar components can be estimated by a set of mathematical equations (Good and Van Oss 1992):

$$\gamma_s^{LW} = \frac{\gamma_l^{LW} \cdot (1 + \cos \Theta)^2}{4} \quad (2)$$

$$\gamma_l \cdot (1 + \cos \Theta) = 2 \cdot \left(\sqrt{\gamma_s^{LW} \cdot \gamma_l^{LW}} + \sqrt{\gamma_s^+ \cdot \gamma_l^-} + \sqrt{\gamma_s^- \cdot \gamma_l^+} \right) \quad (3)$$

$$\gamma_s^{AB} = 2 \cdot \sqrt{\gamma_s^+ \gamma_s^-} \quad (4)$$

where the Lifshitz–van der Waals forces γ^{LW} [mJ/m²], polar γ^{AB} [mJ/m²], acid (electron acceptor) γ^+ [mJ/m²], and base (electron donor) γ^- [mJ/m²] are the components of the surface free energy γ [mJ/m²] and can be calculated from mean values of the apparent contact angle (θ_a), expressed in a somewhat simplified form by the Young's equation:

$$\cos(\theta_a) = \frac{\gamma_{SV} - \gamma_{SL}}{\gamma_{LV}} \quad (5)$$

It is a convention to consider $\theta = 90^\circ$ as a boundary value between hydrophilicity and hydrophobicity. Values less than 90° indicate hydrophilic membrane surfaces with a positive liquid spreading, whereas angle values higher than 90° are measured on hydrophobic membrane surfaces with negative spreading values (Fig. 2). Rolling water droplets can be observed on superhydrophobic surfaces with $\theta > 150^\circ$ and $S < < 0$.

In all cases, the apparent contact angle can be regarded as the result of combined morphological (i.e., tailed and loopy polymer segments, grooves, and pores) and chemical (i.e., functional binding

Membrane Wettability,**Fig. 1** Representative scheme of cohesive forces at an interface**a** $S > 0$ $\theta < 90^\circ$

M

or nonbinding sites) elements. Both two contributions can go to the same or opposite direction, depending on the nature of the chemical and physical forces established at the interface. Normally, large membrane surface affinity toward a liquid produces extensive spreading, while higher surface roughness minimizes it. The roughness factor or rugosity (R) is associated with an irregularity of the membrane surface and can reduce the adhesion between liquid and substrate, causing an increase in the apparent contact angle (Thomas 1999). In this respect, Wenzel and Cassie–Baxter equations describe the wettability better than Young’s equation, which is considered valid for ideal surfaces only (Fig. 3).

In the Wenzel model, the surface grooves are completely filled by the liquid and the contact angle is determined by

$$\cos(\theta_w) = R \left[\frac{\gamma_{SV} - \gamma_{SL}}{\gamma_{LV}} \right] \quad (6)$$

Combining this equation with the Young’s one, a simplified relation can be achieved:

$$\cos(\theta_w) = R \cdot \cos(\theta_a) \quad (7)$$

Instead, in the Cassie–Baxter model, grooves as well as pores are filled by air, which reduces the adhesion line between liquid and substrate, resulting in higher contact angle values:

$$\cos(\theta_{CB}) = f_s \cdot \cos(\theta_a) + f_v \cdot \cos(\theta_v) \quad (8)$$

where θ_a is the angle measured on the flat surface, whereas f_s and f_v are the fractions of the solid and vapor on the surface, respectively.

Some authors have proposed a “zigzag” geometric model that corrects for roughness factor for contact angle measurements, thereby making possible an evaluation of the surface chemistry effects (Taniguchi and Belfort 2002).

Membrane Wettability, Fig. 3 Effects of the roughness factor on the contact line between droplet and surface: (a) a flat surface described by Young's equation, (b) a rough

surface described by Wenzel equation, (c) a pillar surface described by Cassie–Baxter equation, and (d) zigzag profile section responsible for increased surface roughness

Contact angle measurements are powerful tools able to reveal variations of the supramolecular chemistry owing to adsorption, fouling, affinity, or dry–wet switch taking place on the membrane surfaces during separation processes. In this respect, useful indication can be obtained about the opportunity to put in contact membranes with chemical streams without damages and/or special treatments. Cleaning against dirty or chemical contaminations can be monitored as well as energy cohesive can be determined in order to detect the nature of the interfacial forces that control adhesion processes. Also, swelling along with wetting and dewetting phenomena can be studied under the action of specific triggers. Static and dynamic contact angle modes take the advantage of investigating all these supramolecular changes in real time (Gugliuzza and Drioli 2007; Gugliuzza and Drioli 2004, Gugliuzza et al. 2006, 2007). In static mode, a predetermined volume of liquid is placed on the membrane surface and changes against time can be monitored. In dynamic mode, the liquid is constantly pumped into (advancing mode, θ_{adv}) and out (receding mode, θ_{rec}) a droplet in contact with the membrane. The advancing contact angle gives indirect indication about hydrophobic domains distributed throughout the surface; the receding one reveals the ability of local chemical moieties to rearrange when coming in contact with the liquid phase. The

hysteresis expresses the difference between two plateau values, due to chemical and morphological effects at the liquid–surface interface.

Membrane-Based Desalination

Aamer Ali

Department of Environmental and Chemical Engineering, University of Calabria, Rende, Italy

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Desalination (also known as “desalinization” and “desalting”) refers to the removal of salts and other minerals from water. Main drivers for desalination include rapidly expanding population, industrialization, unequal distribution of water resources across the globe, and enriched living standards. On one hand, demand of freshwater is constantly increasing, while on the other hand, the reservoirs of freshwater are becoming contaminated and their size is shrinking. It has been estimated that over one billion people in the world are deprived of clean water and approximately 2.4 billion people are living in water stressed regions. In order to bridge the gap between demand and supply of the freshwater, brackish water, and seawater, desalination has been adopted globally. On the parallel lines, water reuse has been adopted for irrigation, cooling purpose at power generation plants, and industrial process water. The volume of seawater desalination capacities has been recorded as 80 m³/day during 2013 (Villacorte 2014).

Desalination can be accomplished mainly through thermal, chemical, and membrane-based techniques. Thermal desalination is known since centuries, and techniques such as multistage flash (MSF), multi-effect distillation (MED), and thermal vapor compression (TVC) are still in practice in some energy-rich regions. The Middle East accounts for 50 % of the global desalination capacities. Contrary to this, membrane-based processes (mainly reverse osmosis (RO) and to a certain extent nanofiltration (NF)) have dominated the market with 60 % share. NF as a stand-alone process is not effective to produce portable water from seawater, and its use has been restricted only for mildly brackish water

desalination. RO has emerged as a leading technology both for seawater and brackish water desalination, despite the difference in characteristics of the two water sources. What made the RO desalination applicable for practical uses was the development of appropriate membranes with high permeability and selectivity together with improvement of mechanical strength. The large market share of RO and further predicted increase are due to reduction in energy from thermal to membrane desalination (around a factor of 10) which also decreases the production cost of freshwater. Although the energy source has been changed from thermal to electric energy, the main cost breakdown for seawater RO desalination is still the cost of energy. Membrane replacement only accounts for around 10 %.

Despite its widespread application in desalination sector, RO still suffers certain limitations including rigorous feed pretreatment, limited recovery factor, fouling, relatively high energy cost, and brine disposal issue (Greenlee et al. 2009). The basic objective of pretreatment applied is to reduce the fouling tendency of the membrane. Surface water used in seawater desalination has more fouling triggering contaminants and therefore requires more rigorous pretreatment than groundwater. Membrane degradation caused by disinfection treatment applied and biofouling have been considered as big challenges for RO process. New membrane materials with improved chlorine attack resistance are being developed to address the former issue. Seawater desalination capacities located in the coastal areas pose a continuous threat to local environment and marine life due to high salinity level and temperature of the discharged brine.

In order to address the problems associated with reverse osmosis desalination, better energy recovery devices, better membranes, and very large-scale plants with twice the capacities of today's RO desalination plant are being investigated. Moreover, a very interesting approach for improve desalination is the integration of various membrane operations. The combination of innovative and well-established operations for desalination offers highly interesting opportunities. Actual experimental data suggests that, if MD is

operated on the RO retentate, the total amount of desalinated water represents almost 88 % of the feedwater. Additionally, the use of a membrane crystallization allows extracting not only further water but also the minerals contained in the brine streams (e.g., sodium, chlorine, magnesium, sulfate, calcium, potassium, bicarbonate, and eventually also lithium, bromine, etc.). The integration of forward osmosis or reverse electrodialysis for energy production from salinity gradient might be a strategic intensified desalination industrial sector in the future. Integrated approach takes into account energy saving, water rationalization, minimization of resources utilization, and waste production and can contribute significantly to the solution of strategic aspects of industrial productions. Different membrane operations can be coupled in integrated systems for approaching the ambitious objective of “zero liquid discharge” in desalination (Drioli and Criscuoli 2011).

Due to the rapidly growing demand of freshwater, a lot of research activities are being conducted to find new ways to carry on desalination. Emerging processes including electrodeionization, membrane distillation, freeze separation, capacitive deionization, rapid spray evaporation, vacuum distillation, etc. can reshape the desalination system of future. Furthermore, the current desalination techniques will have to cope with new challenges of successful and stable treatment of high salinity streams such as produced water which may contain total dissolved solids many times higher than seawater. The current RO process does not adequately remove some trace elements such as boron. The removal of micropollutant originating from pharmaceutical and personal care products is another challenge to be addressed by the successful desalination technologies of the future.

Membrane-Based Heat and Moisture Recovery

Li-Zhi Zhang

Key Lab of Enhanced Heat Transfer and Energy Conservation, South China University of Technology, Guangzhou, China

Membrane-based heat and moisture recovery (also called membrane-based total heat recovery) is the most innovative device used for energy recovery from ventilation air of buildings. Normally the water vapor content of atmospheric air is small, some tens of grams per kilo of air. Nevertheless, due to the very high heat of vaporization, the latent heat content in air conditioning is of the same order of the sensible one. Due to the fact that the fresh air latent load accounts for 20–40 % of the total load for air conditioning and air conditioning accounts for one third of the total energy use in society, to reduce energy use in treating fresh air is a crucial step to the whole society's sustainable development. Total heat exchangers (or the so-called energy recovery ventilators or enthalpy exchangers) could save a large fraction of energy for cooling and dehumidifying the fresh air since cool and dryness would be recovered from the exhaust stream to the fresh air in summer, as shown in Fig. 1. With total heat exchangers, the efficiency of the existing HVAC systems can be improved either. The reason is that normally the fresh air is dehumidified by cooling coil through condensation followed by a reheating process, which is very energy intensive. This part of energy can be saved if total heat exchangers are installed to reduce the dehumidification load. Besides energy conservation, the total

Membrane-Based Heat and Moisture Recovery,

Fig. 1 Schematic of a membrane total heat exchanger (Zhang 2008, 2013)

heat exchangers have the additional benefits of ensuring sufficient fresh air supply, which is crucial for the prevention of epidemic respiratory diseases like SARS and bird flu.

Membrane-based total heat exchangers have many benefits. They have no moving parts and the reliability is quite high. The duct sealing is easy and the crossover problems can be prevented. The difference between a total heat exchanger and a common sensible-only heat exchanger is that water-permeable membrane plates are used instead of metal plates. Currently, there are two types of vapor-permeable materials: paper and hydrophilic polymer membranes. Paper is cheap, but its moisture efficiency is lower than 0.4. Membranes have higher latent effectiveness above 0.65. The shortcomings are that they are expensive than paper. Developed membranes for heat and moisture recovery include dense membranes, composite membranes, and supported liquid membranes. The structures for total heat exchangers include parallel-plate duct, plate-fin duct, and cross-corrugated duct.

Membrane-Based Liquid Desiccant Air Dehumidification

Li-Zhi Zhang

Key Lab of Enhanced Heat Transfer and Energy Conservation, South China University of Technology, Guangzhou, China

Membrane-based liquid desiccant air dehumidification is the most innovative device used for non-contacting air dehumidification. It is also called membrane contactor for liquid desiccant air dehumidification. Liquid desiccant air dehumidification is one of the most widely used dehumidification technologies for air dehumidification or indoor air humidity control, due to its advantages of high efficiency, no liquid condensate droplets, and its capability of energy storage. Packed beds or packed columns are the common way of processing the air. According to this method, the liquid desiccant is spread down the packings in the column. They provide the large contact areas between the liquid and air stream, on which the liquid is spread. Air stream flows across the packing surfaces. Since the liquid desiccant and the process air are in a direct contact, small liquid desiccant droplets may be carried over by the process air to indoor environment, which is believed to be rather harmful to occupant health, building structure, and furniture. In order to overcome these drawbacks, membrane contactors are

Membrane-Based Liquid Desiccant Air Dehumidification, Fig. 1 Schematic of a membrane contactor for liquid desiccant air dehumidification (Zhang 2008, 2013)

used to replace packed columns. Membranes are used to separate the liquid and the air streams, so it is also called non-contacting air dehumidification. The membranes can prevent the liquid desiccant from crossing over to the process air, while selectively permitting the transport of heat and moisture between the liquid stream and the air stream. The developed membranes include hydrophobic porous membranes and hydrophobic-hydrophilic composite membranes. The structures can be parallel plates or hollow fiber membrane bundles. For liquid-to-air heat and mass exchangers, shell-and-tube structures are suitable. When membranes are made into hollow fibers, they can endure large pressures. Numerous fibers are packed in a shell to form a shell-and-tube structure, which makes the packing densities rather high. Liquid always flows inside the fibers, and gas flows across the bundle. The contact area between the liquid and the gas is very high, which is often used to offset the drawback of slow liquid-air transport coefficients. For such structures, air side pressure drops are usually low and acceptable. Due to tube structure, liquid side can endure large pressures, which makes the driving force high. The benefits are that the pressure drops for both sides are within acceptable levels. The inlet solution is cold and thick. Hygroscopic salt solution like LiCl and CaCl₂ can be used. The dew point for dried air can be $-48\text{ }^{\circ}\text{C}$ (Fig. 1).

Membrane-Cryogenic Hybrid Processes

Marco Scholz

Aachener Verfahrenstechnik – Chemical Process Engineering, RWTH Aachen University, Aachen, Germany

Membrane-cryogenic hybrid processes are processes in which membrane technology and condensation equipment are combined to achieve a gas separation. This type of process is particularly efficient, when at least one component is condensable. Water vapor and higher hydrocarbons are typical gases which can easily be removed from permanent gases by condensation separation.

Membrane-cryogenic processes are particularly interesting when the components which are easy to liquefy permeate faster through the membrane. Here only a fraction of the feed gas has to be chilled. Concerning water almost all membrane materials can be applied. When vapors are to be

separated, rubbery membrane materials should be applied, as the vapor components will permeate faster through the membrane.

The separation in a gas permeation module is determined by kinetics, while the condensation separation is governed by thermodynamic equilibrium. Hence, the outlet concentration of the condensable components from the condensation equipment is determined by the vapor-liquid equilibrium only. It is mainly determined by temperature and pressure. Often, the concentrations of the condensable components are low compared to the concentration of the permanent gases, and, thus, the vapor-liquid equilibrium can be considered as independent of concentration.

Two types of membrane-cryogenic processes can be realized when vapor permeates faster through the membrane than permanent gases. In the first process, the membrane unit performs the main separation, but the permanent gases which should be rejected by the membrane also permeate through the membrane. In order to enhance the recovery of the permanent gases, chilling equipment is applied on the permeate side. Hence, the condensable gases will be removed from the permeate gas and the permanent gases will be recycled.

In the second process, the chilling unit and the gas permeation unit are connected in series. The chilling unit performs the bulk separation, and the gas is further polished in the subsequent gas permeation unit. The permeate stream of the gas permeation module is enriched in condensable components, and this stream is recycled to the chilling unit. Hence, the inlet concentration is increased and the quantity of components which are condensed increases.

Examples of Membrane-Cryogenic Hybrid Processes

The separation of propylene and nitrogen is efficiently done applying a hybrid process in which cryogenic separation and membrane modules are combined (Baker et al. 1998). Rubbery membranes are used and propylene

selectively permeates through the membrane. In this process both the propylene and the nitrogen are to be recovered at high purities. The propylene is obtained from condensation equipment in liquid state so that it has a high purity. The nitrogen purity is controlled by a gas permeation module.

Follmann investigated membrane-cryogenic hybrid processes for carbon dioxide capture (Follmann 2010). Here, chilling and gas permeation membranes are combined to separate carbon dioxide and nitrogen in a postcombustion process. However, driving this hybrid process requires more energy than the conventional amine absorption process.

In the purification of steam cracking products, mixtures of mainly hydrogen, carbon monoxide, methane, and ethylene have to be separated. The hydrogen can be separated in a gas permeation unit where the hydrogen selectively permeates through the membrane (Hopkins et al. 1987). The hydrogen-lean retentate stream is polished in a subsequent cryogenic separation.

Air can be used to produce both high-purity argon and nitrogen (Thorogood et al. 1991). A chilling unit supplies two streams. One is enriched in nitrogen and the other is enriched in oxygen and argon. A gas permeation unit is applied to separate oxygen and argon. Here, the argon preferentially permeates through the membrane, and at least two membrane stages are required to obtain high argon purities.

Synonyms

Pressure retarded osmosis (PRO) for energy generation; Reverse electrodialysis (RED)

Blue energy or the salinity-gradient energy refers to the energy extracted from two streams with different salinity levels. By exploiting the salinity gradient between seawater and freshwater, theoretically, 0.8 kW/m^3 can be extracted which is equivalent to a waterfall falling from a height of 280 m (Post 2009). The maximum extractable energy by mixing two streams with different salinity levels ranges from 0.75 to 14.1 KWh/m^3 of low-salinity streams (Logan et al. 2012). The actual quantities are anyhow lower due to inherent irreversible energy dissipation. Among several approaches being investigated, reverse electrodialysis (RED) and pressure retarded osmosis (PRO) are two most commonly used approaches to harness blue energy. PRO is based upon the flow of water through a semipermeable membrane to produce pressurized water that generates

electricity using mechanical turbines. The operational principle of PRO and RED has been explained in Fig. 1a, b, respectively. The semipermeable membrane ideally retains all the ions and allows the flow of water from low concentration to high concentration increasing the pressure of this stream. A part of high-pressure stream is used to run a turbine that generates electricity, and the rest is used to pressurize saltwater by using a pressure exchanger. RED utilizes ion-exchange membranes for ionic transport that directly generates the current. In RED, cation- and anion-exchange membranes are used to transfer the respective ions from high- to low-concentration solution flowing through alternative channels. The electrochemical potential associated with the movement of positive and negative ions is converted into electric current at electrodes.

Progress in PRO has been retarded by the lack of suitable membranes that could allow the passage of water at adequate rate. Internal concentration polarization (Fig. 2) occurring in the support of layer of membrane limits remarkably water flux and associated power density. Two mechanisms govern the internal concentration polarization: rejection and accumulation of salt present in the dilute stream and diffusive salt diffusion through the membrane from concentrated to dilute solution. The new generation of cellulose acetate membranes originally developed for forward osmosis is capable to achieve power density as high as 5.1 W/m^2 . The unavailability of robust and fouling-resistant membranes with minimum internal concentration polarization and fouling tendency are the main obstacles for economical commercialization of PRO process. The main focused areas for further improving power density of RED include improvement of membrane material, spacing, and architecture. The main challenge for RED is the high cost of RED membranes that is expected to decrease with increase in global demand (Logan et al. 2012). This trend has already been observed for reverse osmosis membranes where new membrane materials, improved fabrication methods, and large production volumes have reduced the membrane cost substantially over the time.

Membranes for CO₂ Capture from Flue Gas

Xuezhong He

Department of Chemical Engineering, Norwegian University of Science and Technology, Trondheim, Sør-Trøndelag, Norway

The control of anthropogenic emissions of greenhouse gases (GHG) is one of the most challenging environmental issues owing to the implications of GHG for global climate change. Among these GHG, CO₂ is the largest contributor in regard of its amount present in the atmosphere contributing to 60 % of global warming effects, although methane and chlorofluorocarbons have much higher greenhouse effect as per mass of gases (Yamasaki 2003). A lot of efforts have been put

on the reduction of CO₂ emission from large CO₂ point sources such as fossil fuel power plants and other industries (e.g., cement, steel and iron production, natural gas sweetening, and biogas upgrading processes). Such plants emit large quantities of CO₂; for example, the fossil fuel power plants are responsible for roughly 40 % of total CO₂ emissions and coal-fired plants being the main contributor. Clearly, coal-fired plants need to be addressed first, especially by retrofitting existing plants.

Different techniques such as chemical absorption (e.g., MEA, MDEA), physical absorption (e.g., Selexol, Rectisol), physical adsorption (e.g., molecular sieves, metal-organic frameworks), cryogenics, and membrane separation could be used for CO₂ capture. Chemical absorption has been widely used in natural gas for over 60 years and separates out relatively high purity CO₂ stream. However, conventional amine absorption technologies are energy intensive and costly, which would result in large incremental costs. National Energy Technology Laboratory (NETL) estimates that amine unit will increase the cost of electricity production by 70 % (Elwell and Grant). Membranes are already an alternative and competitive technology for the selected gas separation processes such as air separation, natural gas sweetening, biogas upgrading, and hydrogen production during the last two or three decades. Membrane technology will become

Membranes for Natural Gas Sweetening

Xuezhong He

Department of Chemical Engineering, Norwegian University of Science and Technology, Trondheim, Sør-Trøndelag, Norway

Natural gas sweetening (CO₂ removal from natural gas) is mandatory to meet the specifications of natural gas grid. Decision on which technology to use for CO₂ removal from natural gas is mainly dependent on process conditions and the crude natural gas composition. Conventional chemical absorption is well known and has been commercially used for CO₂ removal in various processes and considered as a state-of-the-art technology. However, membrane system shows a great

potential for natural gas sweetening since it possesses many advantages such as small footprint, low capital and operating costs, and environmental friendly and exhibits process flexibility even though it has only 5 % of the market today. Membrane unit cost and CH₄ loss are two crucial parameters used for evaluation of membrane process efficiency, which are mainly dependent on the membrane performance and process design. Some representative suppliers of membrane systems using different materials for CO₂ separation from natural gas are shown in Table 1. Although common polymer membranes for natural gas sweetening are still using cellulose acetate/triacetate and polyimide, the novel, high-performance fixed-site-carrier (FSC) membranes showed a great interest for CO₂/CH₄ separation (Deng et al. 2009a).

High-pressure operation is the main challenge for natural gas processing with membrane system. Membrane plasticization is found to be a well-known phenomenon in most polymer membranes which absorb a high content of CO₂ at high pressure (Donohue et al. 1989; Wind et al. 2004), resulting to a significant decrease of CO₂ permeance as well as selectivity of CO₂/CH₄. The possible strategies to overcome membrane plasticization are cross-linking of membrane material (Wind et al. 2002) and fabrication of mechanical strength-enhanced membranes, e.g., mixed matrix membrane, by adding inorganic fillers into polymer matrix. Adams et al. prepared a 50 % (vol.) zeolite 4A/poly(vinyl acetate) (PVAc) MMM for CO₂ separation from natural gas (Adams et al. 2011). They found that the prepared MMMs can approach Robeson CO₂/CH₄ upper bound, and CO₂ permeability

Membranes for Natural Gas Sweetening, Table 1 Representative commercial membrane systems for CO₂ removal from natural gas

Membrane	Material	Company	Module
Separex TM	Cellulose acetate	UOP	Spiral wound

Cytop	Perfluoropolymers	MTR	–
Medal	Polyimide	Air Liquide	Hollow fiber

remained effectively unchanged with a 63 % increase in selectivity compared to pure PVAc. Their membranes showed a promising application in high-pressure natural gas sweetening. Deng et al. reported that carbon nanotubes (CNTs) reinforced PVAm/PVA blend FSC membrane and presented a good CO₂/CH₄ separation performance (Deng et al. 2009b; He et al. 2014). It shows a much strong mechanical strength which could have possibility to maintain a good separation performance even at high pressure.

Process design for CO₂ removal by membrane system from natural gas depends on the membrane permeability and selectivity, CO₂ concentration in feed stream, specific separation requirement, as well as the location of the plant. Peters et al. conducted process design, simulation, and optimization for CO₂ removal from natural gas using HYSYS integrated with an in-house membrane program (ChemBrane) (Peters et al. 2011). They reported that a two-stage membrane system with a CO₂ permeance 0.3 m³ (STP)/(m² h bar) and a CO₂/CH₄ selectivity 40 is comparable to that of amine process. Although the purity of sweet gas is a little low, it can still achieve the sales gas standards (<2 % CO₂ in natural gas). A combination of hybrid processes comprising a membrane system for bulk removal of CO₂ from crude natural gas feed with an amine unit for final purification to reach the pipeline specification (<2 % CO₂) could be the optimal process for natural gas sweetening. Future direction of natural gas sweetening using membrane systems will focus on the development of high-performance membranes with an active layer on the order of 0.1 μm to compete with the other separation methods. In addition, membranes should also have to be resistant to warm and high-pressure operating conditions and mechanically strong. Membrane plasticization and long-term compaction at high pressure should be further investigated. Moreover, how to predict the long-term performance in commercial application based on the short-term lab-scale tests could be a continuing challenge of membrane system for high-pressure natural gas sweetening.

Membranes for Seawater Desalination

Davide Mattia

Department of Chemical Engineering, University of Bath, Bath, UK

Membranes for seawater desalination include several different membrane types based on the diverse technologies used to produce drinkable water from seawater.

Conventional seawater desalination technologies include multistage flash, multi-effect distillation, and vapor compression (collectively known as thermal desalination) and ion exchange. Membrane-based seawater desalination processes include reverse osmosis (RO) where the saline feed is forced through a semipermeable membrane under an external pressure gradient, forward

osmosis (FO) where water permeates through a semipermeable membrane due to a concentration gradient, and electrodialysis where ions permeate through anionic and cationic semipermeable membranes under an external electric field.

Currently, reverse osmosis (RO) plants account for about 70 % of installed plants worldwide, with thermal desalination totaling around 30 % and electrodialysis and ion exchange less than 5 %. Total desalination installed capacity amounts to about 10^8 m³/day, equivalent to about 1 % of the water supply worldwide. Economic analyses have shown that RO plants are competitive compared to thermal installations (Abou Rayan and Khaled 2003), with higher rejection of most solutes, except boron (Cotruvo et al. 2010). This advantage has been further increased in more recent plants with the installation of energy recovery devices and more efficient pumps (Fritzmman et al. 2007).

Reverse osmosis membrane technology has significantly evolved from the first products in the 1950s in terms of materials, form, and modules (Lee et al. 2011). Today, the RO membrane market is dominated by thin-film composite (TFC) membranes consisting of a support layer with large porosity, a microporous interlayer, and a thin selective layer on the upper surface facing the saline feed. This complex structure ensures not only robustness but also ease of processability. Furthermore, it has enabled the use of interfacial polymerization methods to reduce the thickness of the selective layer to minimize transport resistance. The material of the selective barrier layer is generally made of aromatic polyamides, with significant research and commercial investments in finding other suitable polymer compositions. Surface modification of the selective layer is extensively employed to increase chemical resistance and reduce fouling.

Most commercial RO membranes are sold in the spiral wound module configuration, which offers high specific membrane surface area, ease of scale-up, and interchangeability, and can be easily produced from flat sheet TFC membrane (Pearce 2007). Larger modules can also reduce operating and capital costs (Ng et al. 2008), with 16- and 18-in. modules now being offered on the market.

RO membranes require extensive pretreatment steps to remove solids, organic foulants, and, in some cases, chlorine. RO membranes operate at pressures varying from 40 to 70 bar to overcome the osmotic pressure of the saline feed and resistance due to concentration polarization buildup over time. Due to the high pressures applied, RO membranes suffer from compaction as well as significant fouling buildup over time. These factors all contribute to the high energy cost of operating RO plants, despite significant innovation in the last 50 years which has brought RO operations close to the thermodynamic limit (Elimelech and Phillip 2011).

Forward osmosis as a desalination method was first proposed in the 1970s, but the first industrial FO plant has opened only in 2012 in Oman. FO uses a draw solution that has a higher osmotic pressure than seawater to extract water from the saline feed into the draw solution through a semipermeable membrane. Intense research and development is now being focused on novel membranes and draw solutions. Membranes for FO differ from those for RO mainly due to effects of concentration polarization and the need to prevent reverse draw solute permeation. Cellulose acetate membranes, originally developed for RO, have made a comeback for FO uses, particularly due to their hydrophilic surface and good chemical stability (Alsvik and Hägg 2013).

A combination of the two techniques has been recently proposed (Klaysom et al. 2013), though its economic viability and social acceptance are uncertain (Elimelech and Phillip 2011). In this FO-RO hybrid system, wastewater is used as feed in a first FO unit with seawater used as draw solution. The latter is, therefore, diluted before entering the RO stage. The RO concentrate is then fed to a second FO unit as draw solution and, as a consequence, diluted before discharge. To close the cycle, the wastewater feed from the first FO unit is concentrated, thereby reducing its discharge volume as well.

In electrodialysis (ED) an external electric field is used to separate dissolved ions in the saline feed, riving them to oppositely charged ions through ion selective membranes. ED systems consist of a series of cation and anion exchange

membranes separated by spacers through which the concentrate streams and the demineralized water separately flow out of the membrane module. Fouling, which occurs at the electrodes due to the accumulation of ions, can be removed by periodical reversal of the electrodes' polarity.

The charge-based separation mechanism is effective at removing not just salt ions but also nitrates and other charged species (Voutchkov 2013). On the other hand, removal of charge neutral contaminants, such as nutrients or organic substances, is less effective than RO systems. ED is economically competitive compared to RO when TDS of the water source is less than 3,000 mg/L, so far mainly limiting its use to brackish water desalination.

ED membranes tend to be thicker than RO ones and prepared mixing an ion exchange resin with a polymer binder. Requirements for the selection of the resin and binders are low electrical resistance, resistance to osmotic swelling, and long life expectancy (Murray 1995). The latter aspect is crucial as most commercial ED membranes are sold as sealed filter cartridges.

Recent developments and future directions: Alongside continuous optimization of polymeric membranes, there is intense research in novel membrane materials or membrane designs. A promising area of research is the incorporation of carbon nanotubes in thin-film composite membranes to enhance permeability with no compromise on salt rejection (Mattia et al. 2014). In fact, in these RO CNT-TFC membranes, the selectivity is still determined by the selective layer of the TFC, whereas the CNTs, embedded in it, provide a high flux conduit for permeated water molecules. Other nanotube materials, such as boron nitride and silicon carbide, have shown promise in molecular dynamic simulations.

Another emerging class of materials for RO-based desalination is represented by graphene at its derivative, graphene oxide. Initial reports on desalination using graphene oxide membranes show high permeability and salt rejection (Nair et al. 2012), while molecular dynamic simulations have investigated the possibility of high flux/high rejection through nanometer scale defects in a graphene layer (Cohen-Tanugi and Grossman 2012).

In either case it should be noted that the increase in permeability promised by these novel membranes does not automatically translate in a decrease in the energy cost of RO desalination. The latter, in fact, is related to the pressure gradient across the membrane that, as discussed, is already close to the thermodynamic limit. Higher permeability membranes, though, could reduce the footprint of RO plants and decrease the amount of chemicals for membrane cleaning accordingly (Elimelech and Phillip 2011).

Other potential RO membrane materials, at an earlier developmental stage, include aquaporins and polymer dendritic structures (Lee et al. 2011).

Membranes for Solvent Dewatering

Sridhar Sundergopal, Siddhartha Moulik and Harsha Nagar
Membrane Separations Group, Chemical Engineering Division, CSIR-Indian Institute of Chemical Technology, Hyderabad, India

Membranes are selective barriers which separate binary mixtures by selectively allowing one component to pass through it while restricting the other under the influence of a different driving force. Solvent dewatering refers to dehydration of organic liquids to achieve purity level of >99.9 %. Generally chemical feedstocks, solvents, and products of chemical reactions in the liquid phase are very often a complex mixture of organic components and water. Some of these mixtures are difficult to separate since distillation requires entrainers which are hazardous to the environment (van Veen et al. 2001). Isopropanol-water system is one such example which forms an azeotrope at 12.5 wt.% water. Isopropanol has wide and varied applications and therefore solvent dewatering is required. A membrane process such as pervaporation is useful in breaking the azeotrope or dewatering the isopropanol to desired concentration. Another is that it breaks down the azeotrope by the

membrane process followed by distillation to attain final purity. A hybrid process of distillation + pervaporation renders dewatering economical. Two types of membrane processes, pervaporation (PV) and membrane distillation (MD), are used in solvent dewatering. Pervaporation allows separation of close-boiling or azeotropic ethanol-water, dioxane-water, acetic acid-water, etc.

Pervaporation (PV) and vapor permeation (VP): PV process finds extensive application in separation of close boiling liquid mixtures, azeotropes, thermally sensitive aromas/flavors and hazardous compounds besides selective removal of species that are present in trace concentrations. Hydrophilic membranes such as poly(vinyl alcohol) (PVA), poly(acrylonitrile) (PAN), poly(acrylic acid) (PAA), sodium alginate, chitosan, poly(ether imide) (PEI), zeolite, and silica membranes coated on tubular ceramic supports have proved to be suitable for solvent dewatering.

PV is generally the combination of two terms: permeation and evaporation. In the permeation step, water solubilizes and diffuses through the membrane, whereas in evaporation step water gets converted into vapor phase due to pressure drop. Figure 1 displays the mechanism of pervaporation process. On the feed side, the organic solvent-water liquid mixture is in contact with the upper surface of the hydrophilic membrane. Water gets sorbed onto the surface of the hydrophilic membrane, then diffuses through the membrane thickness, and finally desorbs in the form of vapor under vacuum at the downstream permeate side of the barrier, leaving behind the dehydrated solvent as the retentate. VP is a process which is very similar through PV except for the fact that the feed in VP is saturated vapor rather than a liquid as in case of PV. VP is also known as evapomeation and is useful when distillation membrane needs to be combined with membrane process. For example, in case of alcohol-water separation, the azeotropic mixture can be separated by directing the vapors from a simple distillation column through the VP unit which enriches the alcohol concentration and thereby provides the advantage of easy separation of the alcohol-water azeotrope. Thus, in VP the flux would be much higher than PV due to the greater

Membranes for Solvent Dewatering,

Fig. 1 Principle of pervaporation

enthalpy of the feed, and moreover extra unit operation such as condensation of the distillate or preheating of PV feed can be avoided resulting in lower operating cost. In PV the feed becomes colder with time since the enthalpies for evaporation of permeate are supplied by feed itself which means that the feed needs to be preheated.

Membrane distillation (MD): MD also works on the same principle as PV, but the membrane is of hydrophobic and microporous nature. In MD process water diffusion occurs in the form of a non-isothermal transport of water. In this process the membrane has the property to prevent the liquid from passing through the pores until the pressure of the feed exceeds the critical pressure of the porous barrier (Sina et al. 2009). Due to the difference in temperature, vapor pressure gradient is created on both sides of the membrane pores. At the high temperature side of the membrane, evaporation occurs during which vapor is formed that passes through the pores of the hydrophobic membrane, whereas condensation takes place at the low temperature side of the membrane which means water flows from high temperature side to low temperature side. In MD the necessary condition is that liquid water does not pass through the pores of the membrane and only vapor

permeates through the pores. During this process the membrane behaves as a physical support for the liquid-vapor interfaces. The nature of hydrophobic microporous membranes is such that it allows the water vapor to penetrate, but due to the surface tension property, it does not allow liquid water to pass through. The driving force for water transport in this kind of process is a gradient in water chemical potential created by a vapor pressure difference. So in this process, diffusion plays an important role, whereas the role of sorption is negligible. MD is useful for different applications such as desalination of water; concentration of liquid foods, sugar solutions, and beverages; and recovery of fermentation products, mineral acids, and aroma compounds including flavors and fragrances, besides treatment of oily feeds. In this process a hot aqueous feed solution is brought into contact with the membrane which prevents penetration of water into the pores due to its hydrophobic nature, resulting in a vapor-liquid interface at each pore entrance. Figure 2 illustrates how the vapor-liquid interfaces are supported at the pore openings. The value of the contact angle θ of a liquid droplet on an ideal smooth homogeneous surface is described by Young's equation (Madhumala et al. 2014):

Membranes for Solvent Dewatering, Fig. 2 Principle of membrane distillation

Membranes for Solvent Dewatering,

Fig. 3 Schematic of a liquid droplet on a solid surface

$$\gamma_{lv} \cos \theta = \gamma_{sv} - \gamma_{sl} \quad (1)$$

where θ is the contact angle between the liquid and membrane and γ_{lv} , γ_{sv} , and γ_{sl} represent liquid-vapor, solid-vapor, and solid-liquid interfacial tensions, respectively.

A droplet of water on a hydrophobic surface of a polymer film made of say polystyrene (PS), polypropylene (PP), or polytetrafluoroethylene (PTFE) will provide a contact angle which is larger than 90° . If surface active agents or organic materials are dissolved in water, the surface tension of the liquid will decrease. As a result, the contact angle θ will decrease, and if it becomes smaller than 90° , the liquid will wet the solid

surface. A schematic description of contact angle between air, liquid droplet, and solid surface is shown in Fig. 3.

• Experimental setup for PV and MD unit operations

A schematic of PV and MD experimental unit is depicted in Fig. 4. The PV cell consists of two bell-shaped B-24 size glass column reducers/couplers clamped together with externally padded flanges by means of tie rods to give a vacuum-tight arrangement. The top half is used as a feed chamber and the bottom one as a permeate chamber. The membrane is supported by a stainless steel porous plate

Membranes for Solvent Dewatering, Fig. 4 Experimental unit for pervaporation/membrane distillation operations

which is embedded with a mesh of the same material to provide a smooth uniform surface. Teflon gaskets are fixed by means of high vacuum silicone grease on either side of the membrane, and the sandwich is placed between the two glass column couplers and secured tightly.

After fixing the membrane, the cell needs to be installed in the manifold and connected to the permeate line by means of a B-24 glass cone which is fixed to a high vacuum glass valve on one side followed by a glass condenser trap consisting of a small detachable collector. The trap is placed in a Dewar flask containing liquid nitrogen for condensing the permeate vapors. A rotary vacuum pump is used to maintain the permeate side pressure which is measured with an Edwards Mcleod gauge tilting type of scale in the range of 0.01–10 mmHg. High vacuum rubber tubing is used to connect the various

accessories to the experimental manifold. Glass - cone-socket joints are fixed with high vacuum grease. The membrane is soaked in the feed solution overnight to attain equilibrium. During experiments, the upstream side is maintained at atmospheric pressure, and the downstream side vacuum is controlled by adjusting a vent valve for air inlet. The following types of membranes are used for dehydration of organic liquids.

- *Dehydration using polymeric membranes*

Polymeric membranes are widely used in solvent dehydration. The nature of material and chemical structure of the membrane and its substrate determine the performance of the membrane. Mass transfer through such polymeric membranes can be explained on the basis of preferential sorption which is a consequence of inter- and intramolecular structure and diffusion which depends on molecular

size. Hydrophilic membranes act as molecular sieves and preferentially sorb water molecules. When the membrane swells, flux increases as the voids between the polymer chains increase, and membrane selectivity decreases as the larger molecules find it easier to pass through to the other side.

- *Dehydration using inorganic membranes*

There are several advantages of inorganic membranes over polymeric membranes such as higher chemical and thermal stability besides greater flux due to nonporous structure. Inorganic membranes are mainly made from ceramic, zeolite, or their compounds. Shah et al. (2000) used a pervaporation system for dewatering of methanol, ethanol, isopropanol, dimethylformamide (DMF), acetone, and ethyl acetate with the help of hydrophilic inorganic zeolite/sodium alginate composite membrane. Membranes made from ceramic materials can be operated at higher temperatures and in the presence of corrosive solvents where polymeric membranes fail. They also exhibit better mechanical stability and they do not undergo plasticization which helps to maintain a more constant performance with varying feed concentration. However the inorganic membranes are susceptible to sudden impact through

pressurization or depressurization, which is one of their drawbacks. They require much less membrane area compared to polymeric membranes due to the ability to operate at which facilitates higher flux. Inorganic materials can also be operated with highly reactive compounds due to their chemically inert nature.

- *Dehydration using mixed matrix membranes*

Combining the advantages of both polymeric and inorganic membranes with minimization of their individual drawbacks, mixed matrix membranes are being extensively prepared and applied for solvent dehydration. These membranes consist of a polymeric membrane wherein an inorganic material is dispersed and trapped into the polymer matrix. By adding the inorganic material, the mechanical properties of the polymer get improved, and the free volume of the membrane gets increased for faster diffusion of feed molecules. The main advantage of pervaporation is to break the azeotrope without involving any third component or entrainer which is used in conventional process such as azeotropic distillation (Sunitha et al. 2013). Some previous studies on solvent dehydration have been enlisted in Table 1.

In an earlier study reported in literature, Madhumala et al. (2014) used PTFE membrane for membrane distillation-based recovery of hydrochloric acid and glycerol. Banat and Shannag (2000) studied application of MD for recovery of acetone, butanol, and ether solvents from dilute solutions.

of appropriate technology of processing depends on capital and operational costs; waste amount and their characteristics; appointed targets of the process, e.g., the values of decontamination factors; and volume reduction coefficients. Membrane processes can successfully supersede many noneffective conventional methods applied in nuclear industry. But in some instances, they can also complement these methods while improving the parameters of effluents and purification economy.

Efficiency of waste processing can be assessed on the basis of the decontamination factor (DF) and volume reduction coefficient (VRC):

$$DF = \frac{A_o}{A_p}$$

$$VRC = \frac{V_o}{V_R}$$

where A_o is the concentration of radioactivity in the waste before treatment; A_p , concentration of radioactivity in the waste after treatment; V_o , initial volume of the waste; and V_R , final volume of the waste.

Pressure-driven membrane processes (► [Nuclear Waste Processing: Pressure-Driven Membrane Processes](#)) are the most often used for radioactive waste treatment. Such processes like reverse osmosis, nanofiltration, ultrafiltration, and microfiltration have found application in nuclear power plants for the treatment of liquid low and intermediate radioactive wastes, as well as for processing of institutional wastes. The thermal process (nuclear waste processing by thermal processes), namely, membrane distillation, was tested for concentration of low and intermediate radioactive wastes from applications of radioisotopes.

The application of liquid membranes (LM) for selective recovery of some specific radionuclides from waste and process streams was studied including different types of arrangements: bulk, emulsion, and supported liquid membranes (nuclear waste processing by supported liquid membranes). The latter uses membrane contactors

Membranes in Antibiotic Production

Membranes in Nuclear Waste Treatment

Grażyna Zakrzewska-Kołodziej
Institute of Nuclear Chemistry and Technology
Instytut Chemii i Techniki Jądrowej, Warszawa,
Poland

Nuclear fuel cycle and application of radioisotopes in research, medicine, and industry generate various types of liquid waste that needs treatment before discharge to the environment. The choice

to immobilize liquid membrane inside the pores; the other process, which applies the membranes for contacting two phases, is membrane liquid-liquid extraction (solvent extraction). Such a process is advantageous in comparison with conventional extraction carried out in the mixer-settler apparatus, since it uses small volume of extracting agent and avoids phase mixing and formation of emulsion. It was tested for separation of actinides in the back end of the fuel cycle (Pabby et al. 2009).

Electrical potential-driven membrane processes using ion exchange membranes were also found as an application for radioactive waste treatment. They comprise such methods like electroosmosis, electrodialysis, and membrane electrolysis. Electroosmosis was used for dewatering a radioactive sludge after filtration or gravitational sedimentation (International Atomic Energy Agency 1994). With this method, high retention factors with minimal membrane fouling were achieved.

Electrodialysis was studied for removal of radioactive ions from low- and intermediate-level radioactive wastes. Inactive compounds like NaCl, Na₂SO₄, and Ca(NO₃)₂ prevalent in the solution, were used as carriers of radioactive ions, such as ²⁴Na, ⁴²K, ¹³⁷Cs, and ⁹⁰Y, present in the waste in small quantities. The decontamination factors for radioactive ions as high as 105 were achieved in this process. Both polymeric and inorganic ion exchange membranes with a good resistance to radiation were employed. Electrodialysis was considered for separation of molybdenum ions and CO₃²⁻ and HCO₃³⁻ from liquid waste containing uranium in hydrometallurgical uranium ore processing (Lounis and Gavach 1997). It was used in combination with diffusion dialysis for separation of ¹³⁷Cs and ⁹⁰Sr from 3 M nitric acid solutions (Mathur et al. 1998). Another application of electrodialysis in nuclear technologies is salt splitting (e.g., Na₂SO₄ decomposition) in the high saline waste with recovery of acid and base (International Atomic Energy Agency 1994). The process gave 12–25 % solution of sodium sulfate, 20 % NaOH, and 20 % H₂SO₄.

Sodium super ion-conducting ceramic membranes – NaSICON – were applied for separation of sodium from radioactive wastes (Fountain et al. 2008) and Nafion membranes for concentration of ¹³⁷Cs. AFN ion exchange membranes were used for the recovery of boric acid from wastewater (Park and Lee 1995). Ion exchange membranes obtained by radiation grafting of polyacrylic acid on a matrix of polyethylene and Teflon were tested for removal of zirconium from solutions containing uranium (El-Sayed et al. 1999). Novel anion exchange membrane was applied to separate ¹²⁵I and ³⁶Cl ions by electrodialysis (Inoue et al. 2004).

Membranes in the Chlor-Alkali Industry

César Valderrama

Department of Chemical Engineering, Universitat Politècnica de Catalunya-Barcelona Tech (UPC), Barcelona, Catalonia, Spain

Membranes in chlor-alkali industry (also called membranes in chlor-alkali process) is the use of membranes in the production of chlorine (Cl_2) and alkali, sodium hydroxide (NaOH), or potassium hydroxide (KOH) by electrolysis of a sodium chloride solution. Chlorine and caustic soda are products that are widely used in the industry. They are used in producing detergents, herbicides, pesticides, pharmaceuticals, plastics, and soaps. The single largest usage area for chlorine is in the manufacture of polyvinyl chloride (Euro Chlor 2007), while its largest use in inorganic chemicals is for the manufacture of titanium dioxide. In the polyvinyl chloride molecule, more than half its content by weight is from chlorine. The manufacture of some plastics such as polyurethanes and epoxy resins that do not contain chlorine in their molecule also requires chlorine in their process. The main technologies applied for chlor-alkali production are mercury, diaphragm, and membrane cell electrolysis, mainly using sodium chloride (NaCl) as feed or to a lesser extent using potassium chloride (KCl) for the production of potassium hydroxide (Lakshmanan and Murugesan 2014; Euro Chlor 2011).

Membranes in chlor-alkali industry have been used since the 1970s when the development of ion-exchange membranes enabled a new technology to produce chlorine: the membrane electrolysis process. The first ion-exchange membranes were developed at the beginning of the 1970s by DuPont (Nafion) followed by Asahi Glass (Flemion) which installed the first industrial membrane plant in Japan in 1975 due to the pressure of Japanese environmental regulations. Today, it is the most promising and fast-developing technique for the production of chlor-alkali and it will undoubtedly replace the other two techniques in

time. Since 1987 practically 100 % of the new chlor-alkali plants worldwide apply the membrane process. Global chlor-alkali production capacity in 2008 was 62.8 million tons/year, with the fastest growth recorded in China, making China today's largest producer and consumer of chlor-alkali products (IPPC 2014). With the growth in membrane cell and conversion to membrane technology, as at 2011, mercury process capacity stood at below 10 % of global production capacity and is set to decline further. Japan is the first major chlor-alkali-producing country to switch entirely to membrane cells (O'Brien et al. 2005).

In addition to ion-exchange membranes, the chlor-alkali industry represents a potential field of application for other membrane technologies due to the several and complex brine treatments due to the stringent requirements for brine purity imposed by membrane cells and also during the product's recovery stage. The chlor-alkali process can be divided into three major steps: brine preparation and treatment, electrolysis, and finally product recovery as can be seen in Fig. 1.

Brine Preparation and Treatment

The brine process includes the supply of salt, its dissolution, and purification of the resulting brine to the standards required by the cell technology. The first step is the removal of hardness and heavy metals by precipitation with OH^- and CO_3^{2-} . The precipitates form sludge, removed by settling in a clarifier. The clarifier overflow will have some residual suspended solids which are removed by filtration in two steps (primary and polishing). Then, hardness is reduced to less than 20 ppb by ion exchange, using resins developed specifically for this purpose. The final step in brine preparation is acidification. Two kinds of membrane technology are used in this stage, microfiltration and nanofiltration (O'Brien et al. 2005).

Microfiltration

Microfiltration refers to filtration processes that use porous membranes to separate suspended particles with diameters between 0.1 and 10 μm . This

Membranes in the Chlor-Alkali Industry,
Fig. 1 Major steps in membrane cell chlor-alkali process

technology can be used in brine filtration for removal of precipitates in the primary treatment prior to electrolysis. The ultimate achievement in the chlor-alkali brine process would be to take treated brine from the precipitation reactors and filter it directly in a single step to produce clear filtrate. This would combine the functions of the clarifier, the primary filters, and the polishing filters in a single step.

The type of membranes used in this application is made from poly(tetrafluoroethylene) (PTFE) and has the advantages of controlled pore size, great chemical resistance, and low-energy surfaces (Baker 2000; O'Brien et al. 2005). This kind of polymer makes the membrane extremely inert and thus convenient for processing even harsh streams.

Unfortunately, the particles being filtered often foul the membrane by blocking the membrane pores and/or by forming a cake layer on the membrane surface (Mores et al. 2000). One method of reducing membrane fouling is rapid backpulsing.

A backpulse of low-pressure compressed air (ca. 30 kPa) then forces filtrate back through the element and removes the solids from the membrane surface. This method entails reversal of the permeate flow through the membrane for very short periods (typically less than 1 s) at high frequency (typically once every few seconds). The reverse flow can provide in situ cleaning by removing some of the foulants from the membrane surface or pores (O'Brien et al. 2005).

Nanofiltration (NF)

This process is, along with backpulse filtration, another example of the new possibilities in processing that are due to recent developments in the field of membrane technology. At conditions intermediate between those used in ultrafiltration and reverse osmosis, this technology can selectively reject multivalent ions such as sulfate while passing monovalent ions. The polymer NF membranes systematically reject sulfates up to 98–99 % from concentrated electrolyte solutions. At the same time, the rejection of chloride ions is quite low. This very high sulfate rejection from concentrated electrolyte solutions is useful for a number of practical applications, e.g., the sulfate removal from brines in chlor-alkali electrolysis. The process therefore can remove sulfate and other multivalent anions selectively from alkali chloride brines. The rejection of salts by NF membranes is complicated and depends on both molecular size and Donnan exclusion effects caused by the acid groups attached to the polymer backbone. Charged groups tend to exclude ions of the same charge, particularly multivalent ions while being freely permeable to ions of the opposite charge (Baker 2000). Usually, the sulfate/chloride selectivity in NF is explained by a negative membrane fixed charge.

The membranes used in this application are in spiral-wound modules placed in cylindrical housings. The low-sulfate permeate flows through the membranes into spacer channels fabricated from a supporting mesh and follows the spiraling channels into a central collecting tube. The reject, high in sulfate, leaves the end of the module. Parallel installation of modules allows increased capacity, and series installation increases the recovery of

brine. Several reports on the process indicate that typical membrane cell depleted brine can be concentrated to 80–100 g/L Na_2SO_4 . The chloride concentration may remain the same as in the feed solution or actually decline to a lower level. The process has application regardless of the type of chlor-alkali cell in use, and it also can remove sulfate from chlorate plant liquors (O'Brien et al. 2005).

Electrolysis

In the electrolysis process, a chloride-salt solution is decomposed electrolytically by direct current. There are three basic processes for the electrolytic production of chlorine. These three processes are the diaphragm cell process, the mercury cell process, and the membrane cell process (1970) (ion-exchange membranes). Each process represents a different method of keeping the chlorine produced at the anode separate from the caustic soda and hydrogen produced, directly or indirectly, at the cathode (O'Brien et al. 2005).

The Ion-Exchange Membrane

The ion-exchange membrane separates the cathode side from the anode side as shown in Fig. 2.

The membrane currently used in chlor-alkali industry is comprised of two layers to be able to withstand the significantly different conditions on either side of it. The two layers are made of perfluorosulfonic acid and perfluorocarboxylic acid films. Figure 2 shows the membrane cell process. A saturated brine solution that has been previously treated is channeled to the anodic compartment while demineralized water is fed to the cathodic compartment. During the electrolysis, sodium ions and some water permeate through the membrane and enter the cathode compartment. Chlorine gas is formed in the anode. Ion-exchange membranes are classified by their function as a separator; cation-exchange membranes, that contain fixed negatively charged ions, are used in the electrolysis process to prevent the anion transport from the cathode compartment to the anode compartment. The fixed ions of the membrane are in equilibrium with the mobile ions (referred to as counterions) whereas the ions that carry the same charge as the fixed charge (referred to as co-ions) are more or less efficiently excluded from the membrane matrix (Donnan exclusion effect). The most important characteristics of an ion-exchange membrane are high permselectivity for the counterions (exclusion of co-ions), high ionic conductivity, and good mechanical, form, and chemical stability (O'Brien et al. 2005).

M

Membranes in the Chlor-Alkali Industry,

Fig. 2 Membrane cell process in chlor-alkali industry

Product Recovery

Full processing of chlorine gas takes a hot, wet vapor at approximately atmospheric pressure and converts it to a cold, dry liquid under significant positive pressure. The common processing steps therefore are cooling, drying, compression, and liquefaction. Furthermore, electrolytic hydrogen is quite pure and is acceptable for most applications. Normal processing involves cooling, which may also serve to remove entrained caustic, and compression. Hydrogen frequently is cooled by direct contact with brine (O'Brien et al. 2005).

Membranes for Chlorine Separation

In this process the chlorine is purified by liquefaction, this purification step is needed because of impurities in the brine and air leaking into the system during electrolysis. Current technology for the purification of Cl_2 usually involves cooling, drying, compression, and possibly liquefaction, unit operations, which demand heavy and expensive equipment. The separation of gases by thin barriers termed membranes is a dynamic and rapidly growing field. Membranes are being used to separate gases from their mixtures by the differential permeation of the components through them (O'Brien et al. 2005).

The main challenge of this technology is to find a membrane material tough enough to withstand the aggressive chlorine environment at the given process conditions. Additionally the membrane must have an acceptable flux and high selectivity for chlorine compared with the other gaseous components present. Polydimethylsiloxane (PDMS), perfluorinated materials (PTFE and the like), carbon molecular sieve membranes (CMS), and glass membranes have been tested out at laboratory scale and found to be able to withstand the harsh process conditions. Some of these materials showed low permselectivity or low to medium durability, when applied as a gas separation membrane for chlorine separation. However, there are some indications that the membrane challenge may be solved in the future for this separation (Lindbråthen and Hägg 2009).

Electrodialysis in Brine Adaptation for Chlor-Alkali Industry

Brine adaptation for the chlor-alkali industry is a technology strategy available for offsetting the cost by selling the concentrated brine to another industry. From an energy point of view, producing the brine for the chlor-alkali industry starting from a reverse osmosis (RO) concentrate requires less energy to concentrate NaCl than starting from seawater. Moreover, the H_2 obtained could be used in situ for generating electricity, thus, some of this consumption could be self-supplied, which makes this process appropriate for places where energy costs are especially high. Adaptation for the chlor-alkali industry reduces the amount of land required and contributes to reducing capital costs, especially where land is expensive or even not available.

However, divalent cations are also more concentrated in the RO brine and require removal, which involves high costs. This problem has been overcome by producing NaCl and then generating the necessary brine. Tanaka et al. (2003) found that the energy consumption in a salt manufacturing process using electrodialysis (ED) with seawater RO brine was 20 % less than the energy consumption if using seawater. ED is an electro-separation process that uses electrical potential difference as a driving force to move ions through ion-exchange membranes. ED can be used to concentrated brine solutions similar to effluents from the desalination of brackish and industrial water. ED can increase the concentration of a brine solution from 0.2–2 % to 12–20 % with energy consumption in the range of 1–7 kWh/m³.

Further research is necessary in this technological scheme for brine adaptation, especially related to the creation of chlor-alkali plants annexed to desalination facilities. These new plants would give an added value to the generated brines as raw material for the production of Cl_2 , H_2 , and NaOH. Furthermore, chlorine could be used for chlorination of the public water supply. Brine adaptation for the chlor-alkali industry requires processes to concentrate the brine such as ED. It is also necessary to eliminate the divalent cations in brine because they exceed the

specifications for membrane electrolysis. These treatments involve high costs, which can be offset by the products obtained from electrolysis (Morillo et al. 2014).

Membranes Used for Bioreactors

► Bioreactor Membrane

Membranes Used for Membrane Emulsification

Emma Piacentini

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

In membrane emulsification (ME) method, a microporous membrane is used to disperse one of two immiscible liquids into another liquid. Specific membrane properties are required for the preparation of an ideal emulsion most suited to an intended application (Charcosset 2009; Gijsbertsen-Abrahamse et al. 2004). The most important membrane parameters for emulsification are:

- Pore size
For direct membrane emulsification, the average droplet size (d_d) is mainly determined by the pore size (d_p) by a linear relation:

$$d_d = x d_p$$

where x is typically in range of 2–10. Monodispersed emulsions can be generated if the membrane pore size distribution is sufficiently narrow.

- Pore geometry
Droplets uniformity and productivity are influenced by pore geometry. Round, square, and rectangle pores have been applied in droplet preparation. Noncircular pores have superior performance, in terms of size distribution control and throughput, compared to circular pores. Different phenomena such as interfacial interaction/instability could occur associated with pore geometric factors to favor production of uniform particles at a high throughput.
- Membrane surface porosity and inter-pore distance
Droplet uniformity and productivity are influenced by the membrane surface porosity

Membranes Used for Membrane Emulsification, Table 1 Inorganic membranes used in membrane emulsification

Membrane	Wettability	Pore geometry	Porosity (%)	Pore size (mm)	Membrane form	Producer	Producer country
SPG	Hydrophilic/hydrophobic	Symmetric interconnected cylindrical pores	50–60	0.1–20	Tubular and flat	SPG Technology Ltd	Japan
α -Al ₂ O ₃	Hydrophilic	Asymmetric interconnected cylindrical pores	35	0.1	Tubular	Westfalia separator membraflow	Germany
α -Al ₂ O ₃ /ZrO ₂ coated	Hydrophilic	Asymmetric interconnected cylindrical pores	60	0.02–0.1	Tubular	SCT	France
Silicon nitride	Hydrophilic	Asymmetric cylindrical pores	–	0.2–5	Flat	Aquamarijn™	The Netherlands
Nickel	Hydrophilic/hydrophobic	Symmetric circular or rectangular pores	0.05–25	5–40	Tubular and flat	Micropore Technology Ltd	UK

and distance between pores. Membrane porosity should be low enough to prevent pores to be close to one another and therefore droplets coalescence at the membrane surface before droplet detachment. However, low dispersed phase flux is obtained because of the low fraction of active pores.

- Membrane thickness

The droplet size is indirectly affected by the membrane thickness. At a given transmembrane pressure, the dispersed phase flux increases if the membrane thickness is decreased. Droplets could be generated at membrane pore level faster than emulsifier diffusion rate and larger droplet size could be produced.

- Membrane surface wettability

The membrane surface should be wetted with the continuous phase to obtain droplets of the dispersed phase. The dispersed phase contact angle with the membrane wetted with the continuous phase should be higher than 90°. Hydrophilic membranes are suited to making o/w emulsions and hydrophobic membranes for w/o emulsions. If the membrane is not wetted with the dispersed phase, a monodispersed emulsion will be able to be successfully obtained; however low productivity is achieved.

Two types of membranes can be used in ME:

- Static and fixed membranes in which a moving continuous phase promotes the droplet detachment from the membrane surface
- Moving membranes in which the membrane is rotated or vibrated within the otherwise static continuous phase generating the surface shear

The most commonly used membranes for ME are Shirasu porous glass (SPG) membrane and microsieve membranes. SPG membrane is a symmetric membrane with interconnected and tortuous pores, synthesized from a Japanese volcanic ash (Shirasu). SPG membranes are commercially available by SPG Technology Ltd with pore diameters in the range of 0.1–20 μ , tubular or disk shape, hydrophilic and hydrophobic surface. Microsieve membranes differ from conventional membranes by their well-structured morphology and controlled porosity, which results in dispersed phase flux. Typical microsieve membranes used in ME are silicon nitride microsieve membranes and nickel membranes. Ceramic and polymeric membranes are also used. Membranes used for emulsification and some of their characteristics are summarized in Tables 1 and 2.

Tailor-made microengineered membranes having uniform pore size distribution, pore size in the range

Membranes Used for Membrane Emulsification, Table 2 Polymeric membranes used in membrane emulsification

Membrane	Wettability	Pore geometry	Porosity	Pore size	Membrane form	Producer	Producer country
PTFE	Hydrophobic	Symmetric interconnected cylindrical pores	—	1.8	Hollow fiber	Microdyn module	Germany
			79 %	1 mm	Flat	Advatech Tokio Ltd	Japan
			79 %	0.5–5 mm	Flat	Goretex	Japan
Polyamide	Hydrophilic	Asymmetric interconnected tortuous pores	—	10 and 50 kDa	Hollow fiber	Forschstung Institut Berghof	Germany
Polycarbonate	Hydrophilic	Symmetric parallel pores	5–20 %	0.05–12 mm	Flat	Millipore Inc	USA

from nano- to microscale, asymmetric wettability between the pore wall and the detachment surface, and suitable porosity have to be developed in order to fulfill properties required to produce uniform emulsions with target size and high productivity.

Mesophilic Organisms

Chiara Schiraldi and Mario De Rosa
Department of Experimental Medicine, Section of Biotechnology, Medical Histology and Molecular Biology, Second University of Naples, Napoli, Italy

Mesophiles are microorganisms which grow at moderate temperatures between 20 °C and 45 °C and with an optimum growth temperature in the range of 30–39 °C. They are isolated in both soil and water environments; species are found in the Bacteria, Eukarya, and Archaea kingdom. For

instance, many bacterial species involved in biodegradation (i.e., digestion and decomposition of organic matter) are mesophiles. Similarly, most pathogens that are dangerous to animals and humans are growing at the normal human body temperature (37 °C); some of the most risky mesophiles are *Streptococcus pyogenes*, *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Salmonella* sp., *Proteus vulgaris*, and specific strains of *Escherichia coli*. However, most probiotic organisms (living microorganisms that reach intestine and thus confer beneficial effects to the host) are mesophiles; in particular lactic acid bacteria are largely used in the dairy industries; few strains proved to sustain well-being and prevent gastrointestinal disorders are used in food supplements and nutraceutical preparations. Many food transformations and processing are based on the use of mesophilic microorganisms; in fact brewing (beer production) consists in soaking a starch source, like maize, exploiting specific yeast strains to convert it into ethanol. Wine-making is based on the use of yeast and other bacteria (malolactic metabolism), to achieve ethanol fermentation and flavorings. Cheese and yogurt making are often based on lactic acid bacteria fermentation. However, mesophilic bacteria are also involved in food contamination and degradation. For instance, *Listeria monocytogenes* is responsible for meat, salami, and soft-cheese spoilage. *Escherichia coli* and *Clostridium kluyveri* cause food modification and also may be responsible for gastrointestinal disorders.

Mesophiles may duplicate by cell division through mitosis, or by sexual reproduction with a male or female bacteria. At the optimal temperature, with the pH and salinity, mesophiles can double their population in just 20–30 min. Among mesophiles, *Escherichia coli* is the major bacterial platform for expressing heterologous proteins; it has been used to expand plasmid DNA and to express mammalian proteins and also extremophilic enzymes (extremozymes), permitting to increase enzyme yield. For this reason, growing *E. coli* to high densities has been a milestone since the early 1970s, in order to achieve maximum productivity especially in commercially relevant products. Research strategies were focused on improving the cultivation techniques, manipulating the bacteria's physiology, or both. As a result, batch, fed batch, and in situ product removal fermentation techniques had been developed (Zelić et al. 2004). Among these, membrane bioreactor-based strategies proved to be very efficient together with optimization of media composition, and the application of molecular biology methods canceling to grow *E. coli* to cell densities of up to 190 g/l (dry weight) (Nakano et al. 1997; Shiloach and Fass 2005), by preventing acetate accumulation and increasing recombinant product yield. Membrane bioreactor was also successfully used to improve biomass yield of probiotic strain and lactic acid productivity (Schiraldi et al. 2003).

Mesoscopic Transport Simulation

Vasilis Burganos

Institute of Chemical Engineering Sciences,
Foundation for Research and Technology –
Hellas, FORTH/ICE-HT, Patras, Hellas

Mesoscopic transport simulation is a type of conceptual or computational simulation of transport phenomena at the mesoscopic scale. The latter is defined as an intermediate scale between the microscopic scale, which considers molecular configurational details, and macroscopic scale, at which certain types of inhomogeneities or fluctuations have been averaged out. In the area of porous media, mesoscopic simulation of transport phenomena may refer to the pore scale itself, that is, to the scale of a few hundreds of pores or grains or to the scale at which a pore neighborhood is viewed as a thermodynamic point in space. In the former case, the characteristic length of a mesoscopic transport simulator is significantly larger than the atomic dimensions, and, as such, it contains or refers to a large number of molecules of the transported species. As a result, local values of system properties, like density, pressure, temperature, etc., can be defined in a consistent yet statistical manner. In the latter case, a continuum formulation is used to employ spatial averages over length scales much larger than the typical pore or grain scale. The concept of the thermodynamic point or of a representative volume element (RVE) has contributed critically in this direction, sidestepping the need for treating spatial heterogeneities at smaller scales. These are reflected in pore-scale simulations, which are utilized to offer effective values for constitutive parameters that are functions of the local conditions and local structure (Bear 1972). In the context of transport phenomena in membranes, mesoscopic simulations of diffusion, flow, two-phase flow, dispersion, and ionic transport are typical examples of simulations that are performed with reference to finite samples of the membrane material. Once a mesoscopic description of the membrane sample

Mesoscopic Transport Simulation,

Fig. 1 Representative element of porous medium

Representative element of porous medium

is available, transport simulations can lead to the determination of transport coefficients at that scale.

The mesoscopic description of the membrane material may involve a pore model to represent the void space of the membrane, a fiber or grain model to represent the solid phase, or a digitized model of the structure following three-dimensional reconstruction. Different types of numerical tools and simulation techniques have been developed for the solution of problems involving transport phenomena at this scale. Notable examples include the classical numerical solvers for the direct solution of the transport equations complemented by appropriate boundary conditions at the faces of the working domain and at the interface between void and solid or, more generally, between the various phases that comprise the membrane. Typical examples of such equations include the diffusion equation, the heat conduction equation, the Stokes or Navier–Stokes equations for flow problems, the convection–diffusion equation, etc. Another category involves the simulation of the motion of a number of molecule deputies that carry, in an efficient manner, the properties of the actual fluid molecules that are obviously too many to

follow individually. Such methods include the direct simulation Monte Carlo (Bird 1963, 1976, 1994), the dissipative particle dynamics (Hoogerbrugge and Koelman 1992; Moeendarbary et al. 2009), the lattice gas method (Frisch et al. 1986; Wolfram 1986, Rothman and Keller 1988), and the lattice Boltzmann method (Benzi et al. 1992; Chen et al. 1992), which, rather than the fluid molecules themselves, follow the evolution of their probability density function across the lattice. The lattice Boltzmann method is a mesoscopic method that originated from the classical statistical physics and is based on simplified kinetic equations. A rigorous mathematical analysis that starts from the lattice Boltzmann equation has been shown to recover mesoscopic continuity and momentum equations using well-defined features of propagation–collision dynamics. Thanks to the explicit relation with details of the geometry and physics of the problem, complex boundaries and various physicochemical phenomena can be treated. Single- and two-phase flow phenomena with or without phase transition can be studied in the context of membrane separations, including gas separation, filtration, membrane distillation, membrane emulsification, etc. (Fig. 1).

Metal Removal and Recovery by Supported Liquid Membranes

Carlos Moreno

Department of Analytical Chemistry, Faculty of Marine and Environmental Sciences, University of Cádiz, Puerto Real, Spain

Supported liquid membranes are based on the combination between membrane separation techniques and liquid-liquid extraction and also

combining both the extraction and re-extraction processes in a single step. They may be applied for the separation of many chemical species, both organic and inorganic, including metals. In the case of metal separation, they use a three-phase configuration, with a thin layer of organic phase impregnating the pores of a solid membrane (polymeric or ceramic) which separates two aqueous phases of different compositions; one of them is the source phase that contains the metals to be separated and the other one is the receiving solution that normally includes a chemical reagent to facilitate the re-extraction process (Fig. 1).

In most cases, the liquid membrane contains an organic selective reagent that facilitates the transport of metals through it acting as a carrier. This organic reagent may be an ionic (both cationic or anionic) or neutral compound, defining a transport mechanism based on ion exchange or solvation, respectively. Besides, different physical configurations of supported liquid membranes may be used, which can be classified in three groups: flat-sheet membranes, hollow fiber membranes, and, in lower extend, spiral wound modules (Dzygiel and Wiczorek 2010).

The use of supported liquid membranes for metal separation has been mainly restricted to laboratory scale. Large-scale operations of supported liquid membranes have been considered a difficult task, basically due to their low stability under long-term operation, which has been associated to the loss of the organic phase filling the pores of the solid membranes. However, the increasing commercialization of hollow fiber modules may contribute to its industrial application.

In the last few years, big attention has been paid to the use of supported liquid membranes as a

Metal Removal and Recovery by Supported Liquid Membranes,

Fig. 1 Schematic representation of a supported liquid membrane used for metal separation

tool for sample preparation in analytical applications. In this sense, liquid phase microextraction systems based on hollow fibers are normally developed, with special interest in miniaturization and optimization of metal enrichment factors.

Metal-Organic Framework

► ZIF-8 Membrane

Metal-Organic Frameworks (MOFs)

Tania Rodenas
Max Planck Institute für Chemische
Energiekonversion, Mülheim an der Ruhr,
Germany

Metal-organic frameworks (MOFs), also called porous coordination polymers (PCPs), are a class of crystalline solid materials whose structure consists of a regular, two- or three-dimensional network of metal cations or metal oxide clusters (so-called nodes) connected by organic molecules (so-called linkers). Figure 1a depicts conceptually how the three-dimensional structure of a MOF is built by assembling metal (oxide) nodes and organic linkers, while Fig. 1b shows a representative scanning electron micrograph of MOF crystals. First reports on metal-organic frameworks date back to 1959 (Kinoshita et al. 1959). Attention toward this class of materials was boosted in the 1990s by more rational approaches to their “reticular” design and synthesis (Hoskins and Robson 1989). Since then,

extensive research efforts have led to several thousand experimentally reported MOF structures and have notably broadened the scope of their potential applications (MacGillivray 2010; MacGillivray and Lukehart 2014). Generally MOFs are synthesized in solution by reacting a salt of the metal node precursor with the organic linker (precursor) molecules. Conventionally, the driving force for reaction, nucleation, and crystal growth is provided by convective (or microwave) heating. Alternatively, electrochemical and mechanochemical synthesis methods, among others, have been described (Stock and Biswas 2012). The MOF crystal size and morphology can be modified by adjusting the synthesis conditions to alter the relative rates of nucleation and crystal growth processes or to favor growth along certain crystallographic directions.

The internal structure of MOFs displays high mass-specific surface areas (typically in the range of 300–6000 m²/g). It typically defines pores and cavities in the micropore range (<2 nm) or, less often, in the mesopore range (2–50 nm). Owing to the large surface areas and porosities, along with their amenability to be designed with adjustable surface properties and pore sizes, in the range of molecular dimensions, via either the judicious selection of the node and linker building units or post-synthesis modifications, MOFs have been long considered ideal solid adsorbents for separation applications.

The capacity of MOFs to separate molecules is generally ascribed to either one or an interplay of several of the following main mechanisms:

1. The “molecular sieving” effect, by virtue of which certain molecules are prevented from penetrating the pores of the MOF while other molecules can enter and adsorb, depending on their molecular size and/or shape.
2. Selective adsorption based on adsorbate-surface interactions, whereby certain intrinsic properties of the molecules such as their polarity or capacity to establish H-bonds determine different adsorption strengths on the surface of the MOF and therefore the preferential adsorption of certain compounds over others. In certain cases, the selective adsorption of a given

Metal-Organic Frameworks (MOFs), Fig. 1 (a) Schematic representation of how an extended MOF structure is built upon the assembly of metal (oxide) nodes and organic linkers (Adapted from image courtesy of Dr. Christian

J. Doonan (University of Adelaide)). (b) Representative scanning electron micrograph of $\text{NH}_2\text{-MIL-53 (Al)}$ MOF crystals

molecule is favored owing to its distinct capacity to adopt an energetically favored packing on the surface of the MOF adsorbent via not only adsorbate-surface but also adsorbate-adsorbate interactions.

3. Adsorbate-induced framework rearrangements. A number of MOF structures exhibit flexibility, i.e., the capacity of their framework to rearrange upon the uptake of certain adsorbates. Strong interaction of the MOF surface with an adsorbate can contract the framework, resulting in a narrower pore aperture. On the contrary, the framework of certain MOFs can expand when the uptake of an adsorbent surpasses a given threshold, giving rise to a wider pore aperture. The latter is widely known as “gate-opening” effect. Such dynamic MOF structural modifications are often highly selective to certain adsorbates and play a determinant role in the discrimination of molecules via either “molecular sieving” or selective adsorption.

As a result of their outstanding potential for molecular discriminations, metal-organic frameworks are considered a prominent example of solid adsorbents for separation applications both in the gas phase and in the liquid phase (Li et al. 2012). Fine-tuning of the pore size/geometry via either direct synthesis or surface modifications has resulted in MOF materials

capable of discriminating even between stereoisomeric molecules, i.e., those having an identical bond of constituent atoms but differing in the orientation of these atoms in space. Attesting their large potential as functional materials for separation applications, MOF synthesis has recently reached industrial scale (http://www.chemistryviews.org/details/news/861963/1st_Industrial-scale_MOF_Synthesis.html).

MOFs can be applied in adsorption-desorption separations, to which end they are shaped in the form of macroscopic pellets or coated on pre-shaped monoliths or meshes. They have also been explored as constituents of membranes (Pera-Titus 2014). On one hand, continuous, thin-film, pure MOF membranes can be prepared by depositing or growing MOF crystals on a porous substrate, as illustrated in the cross-sectional scanning electron membrane micrograph included in Fig. 2a. On the other hand, *composite* or mixed-matrix membranes incorporating MOF crystals as filler material embedded within a polymer matrix have recently attracted a substantial interest as they potentially combine the easy fabrication and processing of polymeric membranes with the intrinsic molecular discrimination properties of MOFs. Figure 2b (bottom) depicts a FIB-SEM micrograph of the internal cross section of a mixed-matrix membrane incorporating discrete MOF crystals within a continuous polymer matrix.

Metal-Organic Frameworks (MOFs), Fig. 2 (a) Cross-sectional scanning electron micrograph of a membrane incorporating a thin film of MOF crystals on a porous α - Al_2O_3 substrate (Adapted with permission from Ranjan and Tsapatsis (2009), copyright (2009) American Chemical Society). Metathesis Norbornene Polymer-Based Membrane Materials

Yuri Yampolskii

A.V. Topchiev Institute of Petrochemical Synthesis, Russian Academy of Sciences, Moscow, Russia

Norbornene and its derivatives are strained bicycles, so their ring-opening polymerization

is thermodynamically favored, so the reaction proceeds easily and with high yields. Numerous metathesis polynorbornenes with different side groups have been prepared and their gas permeation parameters studied (Finkelshtein et al. 2011; Yampolskii 2010). Purely

hydrocarbon polynorbornene has relatively low gas permeability ($P(\text{O}_2) = 2.8$ Barrer). Introduction of one or two bulky nonpolar SiMe_3 groups results in significant increase in gas permeability: the values of $P(\text{O}_2)$ are 30 and 95 Barrer, respectively. On the other hand, appearance of a compact and polar CN group leads to reduction of gas permeability: $P(\text{O}_2) = 0.53$ Barrer. The cis/trans configuration of the double bonds of metathesis norbornene polymers affects gas permeability; the highest values are observed for cis/trans ratio close to unity. The appearance of double bonds in the main chains decreases chemical stability of the polymers: especially unstable is non-substituted metathesis polynorbornene. On the Robeson diagrams, the data points characteristic for various metathesis polynorbornenes are located below the upper bounds, so these polymers are not attractive materials for gas separation. However, their studies provided much information on structure–property relations of potential membrane materials.

Microalgae Concentration

Carles Torras Font

Bioenergy and Biofuels, Catalonia Institute for Energy Research (IREC), Tarragona, Catalonia, Spain

Second-generation biofuels are those obtained from feedstocks, which their main characteristic is that they do not compete with food industry (Schenk et al. 2008). One of these feedstocks is microalgae (Chisti 2010). This biomass is highly considered nowadays because of other several advantages: microalgae offer a rapid growth,

they possess high lipid contents, marine as well as freshwater species can be used, etc. (Miao and Wu 2006; Rosenberg et al. 2008).

The process to produce biodiesel from microalgae comprises several steps: microalgae cultivation, microalgae concentration, cell disruption, lipid extraction and purification, and transesterification (Chisti 2007). They imply a significant cost, which makes the process economical unfeasible if only biofuel is going to be obtained (Amer et al. 2011). Thus, other products such as nutritional, cosmetic, or pharmacological ones may be considered as well as alcohols (Harun et al. 2010). Considering several products to be obtained responds to the biorefining concept. A bottleneck in the biorefining process deals with microalgae concentration. In the previous step (cultivation), concentrations usually below 1 g/L are obtained, which is approximately 1,000 ppm. Thus, to obtain dry biomass, the major part of the volume should be removed, achieving a reduction of an order of magnitude of 3. There are several techniques that can be applied to concentrate microalgae. Classic ones are sedimentation, filtration, and centrifugation (Molina Grima et al. 2003). Sedimentation is the cheapest one, but it consumes time or flocculants and only achieves a concentration factor between 2 and 4 approx. (which is significant) (Şirin et al. 2011). Centrifugation is the most effective method, but it is also the one that consumes more energy. In the past years, membrane filtration has gained attention due to advances in this technology.

Due to the size of the microalgae cells (almost all above 1 μm), microfiltration can achieve complete rejection of the biomass, and low transmembrane pressures may be used (which is an advantage to minimize the energy needed). Also, the medium is chemically low aggressive to the membrane. Because of these conditions, low-cost membrane materials may be used. But a main problem of using membrane filtration in microalgae concentration is the severe fouling that occurs, which dramatically reduces permeability (Rickman et al. 2012). Decrements up to 99 % have been measured (Rios et al. 2011). Research is currently being performed to reduce the mentioned phenomena. Some works

Microalgae Concentration, Fig. 1 Rotatory membrane filtration setup containing membranes after a microalgae concentration experiment

demonstrated that ultrafiltration may be suitable to reduce this effect (Zhang et al. 2010). Other works propose the use of dynamic systems, which enhances the shear stress over the membrane, and promising results have been reported, reducing fouling significantly (Fig. 1). Also, combination of sedimentation and membrane filtration improves performance (Ríos et al. 2012). Other noticeable works are being performed regarding submerged membrane systems (Bilad et al. 2012), in which cultivation and concentration is being performed simultaneously.

Microcapsule Membranes

Zhongyi Jiang¹, Xiaoli Wang¹, Hong Wu¹ and Jiafu Shi²

¹School of Chemical Engineering and Technology, Tianjin University, Nankai, Tianjin, China

²School of Environment Science and Engineering, Tianjin University, Tianjin, China

Definition

Microcapsule is defined as a hollow microsphere comprising large interior void and semipermeable

shells. The interior void serves as storage space or reaction chamber, while the shell protects the bioactive materials/nanoparticles in the interior void from the attack of surrounding environment or controls the transfer of substance in/out the microcapsule. Till now, microcapsule with single shell, double shells, and multiple shells as well as yolk-in-shell structure has been designed and prepared. Since the shell of the microcapsule often possesses nanometer/micrometer thickness and distinct semipermeable property, it fits the typical features of membrane. Therefore, microcapsule shell can be also called **microcapsule membrane**, which was first introduced by Chang in 1960s (Chang 1964).

Characteristics

Microcapsule membrane can be categorized into inorganic, organic, and inorganic–organic hybrid membranes based on the material composition. Inorganic microcapsule membrane usually possesses porous structure and high mechanical stability, which is often synthesized under relatively harsh conditions (e.g., hydrothermal treatment, calcinations, or organic solvent treatment). In comparison, the synthesis of organic microcapsule membrane (mainly self-assembly of amphipathic polymer, layer-by-layer self-assembly, or surface polymerization) is often conducted under rather mild conditions; however, the mechanical stability of organic microcapsule membrane is usually much lower than that of inorganic microcapsule membrane as a result of lack of stiff blocks. Recently, incorporating inorganic components/moieties into organic microcapsule membrane has been demonstrated as a facile, generic to enhance the mechanical stability. Moreover, considering the advantage that hybridization could offer new opportunities to create multifunctional materials with unique properties by combining the merits of inorganic and organic building blocks, hybrid microcapsule membrane may win more promising applications in the future.

Microcapsule membrane has single-, double-, or multiple-layered structure. Single-layered

microcapsule membrane is usually composed of homogeneous polymers or inorganics, while double-layered microcapsule membrane is often composed of two separate layers with different kinds of materials. Multiple-layered microcapsule membrane mainly refers to the microcapsule membrane which is composed of multilayers through the alternative deposition/self-assembly of two kinds of oppositely charged polymers, polymer/inorganic hybrids.

Microcapsule has been applied in diverse areas, including biocatalysis, drug delivery, pollutants removal, biosensing, etc., where microcapsule membrane plays the crucial role in governing the overall performance of the microcapsule. For instance, Jiang et al. prepared protamine–titania hybrid microcapsule membrane and encapsulated the biocatalyst enzyme in the capsule lumen. The enhanced recycling stability of enzyme was due to the high mechanical stability of microcapsule membrane (Jiang et al. 2009). Caruso et al. developed a redox-responsive microcapsule membrane and encapsulated hydrophobic cargo in the capsule lumen. The cargo could be released in simulated intracellular conditions, which were ascribed to reversible disulfide linkages of membrane materials (Yan et al. 2011). Kreft et al. designed a light-responsive microcapsule membrane and encapsulated dextran in the capsules. The dextran is released when near-infrared laser light illuminated the capsules, which was ascribed to the incorporation of light-absorbing gold nanoparticles into the microcapsule membrane (Kreft et al. 2007). Li et al. reported that the porous MnO₂ microcapsules showed good ability to remove an organic pollutant (azo dye Congo red) in wastewater, which was ascribed to the excellent dye adsorption capability of porous microcapsule membrane (Fei et al. 2008). Yu et al. prepared polymeric microcapsule membrane and encapsulated rhodamine 6G. The capsules rapidly released rhodamine 6G in ethanol but cannot release in aqueous solution. This was because the charge density of microcapsule membrane in ethanol was markedly decreased due to its low dielectric constant as compared to that in aqueous solution (Yu et al. 2009).

Microencapsulation is the technology of packaging individual particles of solid, liquid, or gaseous materials in capsules in the micrometer to millimeter range, which can release their contents at controlled rates or under specific conditions (Chabala et al. 1978). Upon microencapsulation, liquid and gaseous materials are more easily handled since they acquire a solid-like form; it may also afford extra protection, owing to the barrier around hazardous materials.

Processes of microencapsulation have traditionally been categorized into two groups: chemical and physical (or mechanical) processes (Prasad and Sarkar 1992). Indication of which category is at stake may come from whether the

microcapsules are produced in a liquid-containing tank as in chemical processes, as opposed to physical processes that employ a gas phase. There are in practice seven major methods of microcapsule production: coacervation, interfacial polymerization, phase separation, spray drying, fluid bed coating, centrifugal extrusion, and rotational suspension.

Coacervation takes advantage of the reaction between aqueous solutions of cationic and anionic polymers, e.g., gelatin and Arabic gum; such polymers form a concentrated, complex phase called coacervate – which maintains an equilibrium with a dilute supernatant phase. As the water-immiscible core material is introduced into the system, thin films of coacervate coat the dispersed droplets of core material, which are then solidified – thus conferring a harvestable form to the capsules (Klaassen and Jansen 2001). This is probably the most common method of microencapsulation (Ocak et al. 2011); its major advantage is the very high payload (up to 99 %) and controlled release possibilities (Jun-Xia et al. 2011).

The method of interfacial polymerization is characterized by membrane formation via rapid polymerization of monomers at the surface of the particles of (dispersed) core material. A multifunctional monomer is accordingly dissolved in the core material, and this solution is dispersed in an aqueous phase; a reactant with the monomer is added to the aqueous phase, so polymerization quickly ensues at the surfaces of the core particles to eventually form the wall. This method is appropriate for preparation of bigger microcapsules, although the commercial size ranges are 20–30 mm and 3–6 mm.

Phase separation is generally grouped with other chemical encapsulation techniques, despite realization that no actual chemical reaction is usually involved in the process. It utilizes two polymers soluble in a common solvent, but which do not mix with each other in solution; hence, they form two separate phases – one rich in the polymer intended to form the membrane, and the other rich in the incompatible polymer meant to induce phase separation. The latter will not be a part of the finished microcapsule membrane, except for traces caught inside the capsule as impurities.

During spray drying, an emulsion is prepared by dispersing the core material (usually an oil or active ingredient immiscible with water) into a concentrated solution of membrane material until the desired size of drops is attained. This emulsion is then atomized into a spray of droplets by pumping the slurry through a rotating disk into the heated compartment of a spray drier: the water portion of the emulsion consequently evaporates, thus yielding dried microcapsules of variable shape and containing scattered droplets of core material. The microcapsules are finally collected via continuous discharge from the spray-drying chamber.

Fluid bed coating is restricted to encapsulation of solid core materials, including liquids absorbed into porous solids. Such particles are suspended on a jet of air and then covered by a spray of liquid coating material; the microcapsules are then moved to an area to allow solidification of their membranes via cooling or solvent vaporization. The process of suspending, spraying, and cooling may be iterated until the walls attain the intended thickness. When the spray nozzle is located at the bottom of the fluidized bed of particles, the process is usually known as the Wurster process.

Centrifugal extrusion processes generally lead to microcapsules of a larger size, typically from 250 μm up to a few mm. The core and membrane materials (which are supposed to be immiscible) are pushed through a spinning two-fluid nozzle; this procedure forms an unbroken rope that naturally splits into round droplets directly after clearing the nozzle. The continuous walls of these droplets are solidified either via cooling or by a gelling bath depending on the composition and features of the coating material.

When applying the rotational suspension separation (or spinning disk) method, the internal phase is dispersed into the liquid wall material – and the mixture is admitted onto a turning disk. Droplets of pure membrane material are thrown off of the rim of that disk – along with discrete particles of core material enclosed in a skin of wall material. After solidification by cooling, the microcapsules are collected separately from the particles of membrane material.

Microcapsules

Angela C. Macedo¹ and F. Xavier Malcata²

¹LEPABE – Laboratory of Engineering of Processes, Environment, Biotechnology and Energy, University of Porto, Porto, Portugal

²DEQ – Department of Chemical Engineering and LEPABE – Laboratory of Engineering of Processes, Environment, Biotechnology and Energy, University of Porto, Porto, Portugal

Microcapsules are discrete portions of an aqueous medium (core) suspended in another aqueous medium, with immiscibility (and hence stability) being assured usually by a lipid layer (membrane) that resembles the phospholipid bilayer of cell membranes. They are often spherically shaped with a continuous membrane surrounding the core, but may take asymmetrical shapes – e.g., with a number of smaller droplets of the core material embedded throughout the microcapsule; microcapsules may also have one or multiple walls around the core, arranged in strata of varying thickness. The core – i.e., the encapsulated substance – has also been termed active ingredient, nucleus, or internal phase; the membrane – i.e., the encapsulating material – is also referred to as coating or wall (Jyothi et al. 2009).

The purpose of microencapsulation is to confine the core material within the capsule membrane and

protect it. Alternatively, core materials may be encapsulated so that they will be released gradually through the membrane (known as controlled release or diffusion) or when release is intended to occur after a given period of time – upon a change in external conditions that trigger the wall to rupture, melt, or dissolve. Microcapsules can be classified, according to the type of membrane, as slow release, impermeable, and smart (Jackson and Lee 1991).

In the case of slow-release membranes, the encapsulated component is released from the capsules for a longer time, depending on the final usage intended therefore. The release time depends on the membrane type – in particular its composition and thickness – and may vary from few days to several months (Marini et al. 1991). The core component may be water- or solvent-based and may assume a solid or a liquid state. Applications that regularly resort to such a type of membrane are fragrances and flavors, pesticides, and reactive chemicals. An example of the former is chewing gum – in which flavors are supposed to last longer than the first bites. Another example is when flavorings are comprised of two reactive components that should not react and thus lose their flavor potential prematurely; in this case, the two components are microencapsulated individually. Pesticides are also encapsulated to bring about release over time, thus allowing farmers to apply them less often and at lower (and thus less toxic) concentrations than in a single use; the environment is better protected, and a more efficient strategy for pest control results. Many varieties of oral and injected pharmaceutical formulations are microencapsulated as well – not only to effect release of the active component(s) over a longer period of time but also to guarantee release only at certain locations in the body. One example is aspirin, which can cause peptic ulcers and bleeding if doses are introduced all at once: slow release decreases its detrimental risks on the stomachal mucosa (Arshady 1993).

Impermeable membranes have the active component encapsulated inside the membrane; the chief purpose is to prevent release and thus

assure complete isolation from the environment. This solution has been proven useful for phase change materials targeted at textile and building industries: the said materials absorb or release heat in response to changes in environmental temperatures – when temperatures rise, they melt thus absorbing excess heat and causing a sensation of cool; conversely, as temperatures fall, phase change materials release heat as they solidify, thus providing a sensation of warmth. This unique property of microencapsulated phase change materials can be harnessed to increase the comfort level of users of sports equipment and military clothing; they have even been used in NASA-patented thermal protection systems for spacecraft. Additionally, the use of impermeable membranes is useful in retaining volatile flavors: encapsulation extends the shelf life of the food product, by retaining flavors that would otherwise evaporate and be readily lost.

Finally, when the core substances should be released only in certain circumstances (e.g., when pH or temperature changes or when exposed to mechanical forces), smart membranes are selected. Successful examples are microencapsulated fragrances that operate on the principle of scratch and sniff for release and some flavorings that must be protected from oxidation caused by exposure to light – so they should not be released prior to mastication (Obeidat 2009).

Microchannel Emulsification

Goran T. Vladisavljević¹, Isao Kobayashi² and Mitsutoshi Nakajima³

¹Department of Chemical Engineering, Loughborough University, Loughborough, Leicestershire, UK

²National Food Research Institute, National Agriculture and Food Research Organization, Tsukuba, Ibaraki, Japan

³Faculty of Life and Environmental Sciences, University of Tsukuba, Tsukuba, Ibaraki, Japan

Microchannel (MC) emulsification is a process of forming emulsions by injecting a dispersed phase through a multitude of microfabricated MC arrays into the continuous phase. Single-crystal silicon MC arrays can be fabricated in the form of horizontal grooves (Kikuchi et al. 1992) or vertical straight-through holes (Kobayashi et al. 2002).

Grooved-type MC plates are fabricated by photolithography and anisotropic wet etching and can be used in dead-end or cross-flow configuration. In a dead-end module (Fig. 1a), parallel grooves fabricated on a terrace are arranged on all four sides of the plate. The dispersed phase supplied through a central hole is forced to flow through MCs, because the plate is sealed with a transparent cover plate. The dispersed phase takes a disklike shape on terrace, and this shape is characterized by a higher interfacial area per unit volume than a spherical shape, resulting in hydrodynamic instability. This instability is a driving force for spontaneous transformation of dispersed phase into spherical droplets (Sugiura et al. 2002).

Dead-end modules provide a dispersed phase flow rate less than 0.1 mL h^{-1} , due to limited number of MCs (less than 2,000). Cross-flow modules with grooved MC arrays are suitable for higher production scales because multiple cross-flow channels with MC arrays can be incorporated on a single plate (Kobayashi et al. 2010). The

Microchannel Emulsification, Fig. 1 Grooved-type MC plates for MC emulsification (Published with permission from Vladisavljević et al. 2012)

Microchannel Emulsification, Fig. 2 Straight-through MC plates for MC emulsification (Published with permission from Vladislavjević et al. 2012)

simplest cross-flow module (Fig. 1b) has only one cross-flow channel and two holes at its both ends for introduction and withdrawal of the continuous phase. The purpose of cross flow is to collect droplets from the module and not to control the droplet size. In the dripping regime, the droplet size is independent on the flow rate of dispersed or continuous phase. Cross-flow MC plates with multiple cross-flow channels are available with a maximum cross section of 60×60 mm and 12,000 MCs arranged in 14 parallel arrays (Kobayashi et al. 2010).

Modules with grooved-type plates have a limited throughput, because MCs are arranged on the plate surface in longitudinal direction, and feed channels for the dispersed and continuous phase are provided on the plate surface. A vertical array of straight-through MCs fabricated by photolithography and deep reactive ion etching allows better utilization of the plate surface resulting in significantly higher throughputs. Straight-through MCs may have a symmetric and asymmetric structure. Symmetric MCs (Fig. 2a) are of the same size and shape (e.g., circular or rectangular) along the whole cross section of the plate. Rectangular MCs provide higher droplet size uniformity than circular MCs, and an aspect ratio of the slots should be at least 3 (Kobayashi et al. 2004). Asymmetric MC plate has circular channels on the upstream (bottom) side and slots on the

downstream (top) side (Fig. 2b). Asymmetric plate is useful when the dispersed phase viscosity is less than 1 mPa s, e.g., when the dispersed phase is a volatile hydrocarbon (Kobayashi et al. 2005). Straight-through micronozzle (MN) array (Fig. 2c) are used to increase the velocity of continuous phase around the growing droplets during detachment, because the channel outlets are above the plate surface, which could be useful if the viscosity of the dispersed phase is high (Sugiura et al. 2005).

Microencapsulation Synonym: Microentrapment

► Encapsulation Application

Microfiltration (MF)

Sayed S. Madaeni
Membrane Research Center, Chemical
Engineering Department, Razi University,
Kermanshah, Iran

General

Microfiltration (MF) is a pressure-driven membrane-based process separating suspended solids and fine particulates in the range of 0.1–10 μm from liquid. The vast size range covers a wide variety of industrial and natural compounds and particles. Microfiltration is able to effectively remove colloids, microparticles, microorganism, and macromolecules from suspensions. The efficiency and cost of microfiltration depends on permeability measured as flux and selectivity tabulated as rejection. Numerous factors affecting these two vital parameters including membrane characteristics

(material, morphology, and pore size) and operating parameters such as transmembrane pressure, cross-flow velocity, and feed properties (concentration, temperature, pH, ionic strength, surface chemistry).

The efficient microfiltration is widely utilized in food and beverage industries, biotechnology, and water and wastewater treatment to significantly remove turbidity, bacteria, and protozoa from water and wastewater. Moreover, several published studies reported partial virus removal by MF (Madaeni et al. 1995).

This technology has several advantages including high selectivity, high product quality, fast operation, small space requirement, continuous and fast operation, ease of scale-up, low running costs, and moderate capital investment. Moreover, microfiltration processes are compatible with the environmental standards due to no formation of by-product and limited usage of chemical additives.

Theoretical approaches are able to predict the performance of microfiltration process using appropriate models including mass transfer, osmotic pressure, gel polarization, boundary layer adsorption, Brownian diffusion, shear-induced diffusion, inertial lift, and surface transport models. The estimation limitations are complexity of mathematical equations, requirement of experimental data for verification, prediction for steady-state flux only, and validation for certain feed and conditions.

Applications

Microfiltration is widely employed for filtering numerous varieties of particles including microorganisms such as algae, fungi, protozoa, bacteria, and viruses.

Viruses are roughly ten times smaller than the pores of microfiltration membranes, i.e., they are small enough to pass through the membranes. However, it has been demonstrated (Madaeni et al. 1995) that hydrophobic microfiltration membrane with the pore size of 220 nm is capable to

remove poliovirus with the size of 20 nm significantly (greater than 99 %). Similar results were found for animal viruses such as FMD and IBR (Madaeni et al. 2013).

Although ultrafiltration membrane is able to completely retain the viruses, the main benefit for microfiltration membrane is higher flux. Virus removal depends on membrane characteristics including surface properties and interfacial properties of viral particles. An appropriate membrane structure, i.e., thick multilayered with porous structure, improves the virus trapping capacity. Moreover, interactions of viruses with the surfaces of membranes improve the removal efficiency. This includes electrostatic and hydrophobic interactions. High retention is obtained with a hydrophobic membrane compared to hydrophilic due to the hydrophobic interaction. Preconditioning of the virus suspension influences the removal capability. Aggregation around the isoelectric point of a virus or in the presence of salt improves the rejection of viruses. The aggregation is significantly improved by manipulating the ionic strength and pH of the feed.

The top priority aim in water treatment is finding new techniques to produce water without formation of by-product and with limited usage of chemicals. This can be achieved by microfiltration which is used to remove suspended solids from water and wastewater. Membrane technology is able to meet the needs for higher productivity and lower cost in biotechnology.

Oily wastewaters containing surfactants, cosurfactants, various additives such as antifoaming agents, and bactericides are among the major environmental pollutants which require purification for reuse and protection of the environment. The conventional procedures exhibit disadvantages including low efficiency, high-energy consumption, high operation costs, and corrosion. Moreover, sometimes the non-reacted chemicals are found in the final wastewater. Microfiltration has been employed for successful treatment of oily wastewaters using both polymeric and ceramic membranes. The latter may be applied at elevated temperature, harsh

chemical environment with uncomplicated regeneration procedure.

Considerable quantities of water, after industrial and domestic use, are discharged in rivers, lakes, and sea. Very often the discharged water causes pollution of surface and underground water. Membrane processes are among the purification techniques to significantly reduce the volume of the polluted water.

In wastewater treatment, controls of discharges require superior solutions compared to conventional biological treatment. One possible solution is the replacement of a secondary sedimentation by suspended microorganisms on the surface of a microfiltration membrane. When large particles like microbial flocks are present in the wastewater, a layer of microorganisms is accumulated on the membrane surface which is known as dynamic membrane.

Microfiltration with many applications in food industry can be used in fruit juice clarification, dairy applications, selective separation of micellar casein, fractionation of milk fat, removal of whey fat, cheese brine purification, separating whole milk into cream and skim milk, and sterilization by reducing bacterial level. The separation of bacteria, spores, yeast, and molds from milk by microfiltration has been further confirmed.

However, membrane fouling and consequent flux reduction due to precipitation of available feed components in membrane pores or on membrane surface are the major obstacle for wide utilization of membrane separation in general and microfiltration in particular.

Hybrid Processes

In addition to direct application of microfiltration membrane, a possible way for improving the process performance is to combine membrane with conventional techniques as hybrid systems. In many cases, the improved hybrid system is able to carry out the desired separation and/or provides higher efficiency compared to the sum of individual stages.

A few examples are presented here. An outstanding application of microfiltration is sterilization of temperature-sensitive solutions such as biologic liquids. However, microfiltration membranes are not able to remove all microorganisms from a solution. Moreover, nano-silver particles exhibit antibacterial capability. Membrane combination with nano-silver results in complete sterilization of the feed (Madaeni and Akbarzadeh Arbatan 2010).

Around 6-log reduction can be achieved for the removal of bacteriophages (bacterial viruses) using microfiltration membrane in combination with coagulation. Microfiltration membranes in combination with bacteria may be employed for degradation of organic contaminants, heavy metals, and inorganic materials in wastewater. The elimination efficiency depends on the specifications of bacteria (type, activity, and surface property) and membrane. Some bacteria such as *Pseudomonas putida* are able to treat heavy metal pollution in industrial sewages or degrade organics, e.g., toluene. For higher removal efficiency, membrane can be coupled with lime as a coagulant for the precipitation of heavy metals, NaOH, and ion-exchange resin. The hybrid process of activated carbon and microfiltration utilizes the capability of activated carbon to adsorb impurities and the ability of membranes for removal of microorganisms and particles.

The integrated membrane systems based on combination of microfiltration and other membrane process such as ultrafiltration or nanofiltration can be conducted for efficient purification and/or as a pre-filtration step for minimization of system's fouling.

Microfiltration Membrane

Sayed S. Madaeni

Membrane Research Center, Chemical Engineering Department, Razi University, Kermanshah, Iran

General

The core of microfiltration process is a thin (10–1,000 μm) porous (0.1–10 μm) polymeric or ceramic membrane. The detailed morphology or structure and physical and chemical characteristics or properties of the membrane influence the separation capability.

Electron microscopy images of surface and cross-section of a membrane are widely accepted for visualization of membrane structure. The membrane surface may change from a smooth to a rough appearance. The membrane pores are extensively varied from hole-like pores (Fig. 1) to tortuous openings (Fig. 2). The shapes and sizes of the membrane pores are greatly changed depending on the point by point preparation procedures and conditions.

The membrane consists of two distinct parts (Fig. 3). The thin (around 1 μm) skin layer is the main segment conducting the separation process and the thick (around 100 μm) support provides mechanical stability. In many cases an intermediate layer exists between the two main layers. The skin layer includes tiny membrane pores. The very large openings in the support do not primarily influence the separation capability. The main limitation for large or small pores in the support is mechanical stability. However, recent studies indicate that any part of the membrane including support may have impact on the membrane performance (Madaeni et al. 2012).

The membrane characteristics and morphology affect the performance. This includes but not limited to the characteristics of membrane material (polymer, ceramic), pores (size and shape), surface (charge, smoothness), preparation procedures and conditions, etc.

Microfiltration Membrane,

Fig. 1 Surface of microfiltration membrane showing the hole-like pores

Microfiltration membranes are used for treatment of water containing particles, colloids, oil, and microorganisms, sterilization of liquids by reducing bacterial level, clarification of fruit juice, purification of cheese brine, separation of pharmaceutical materials, fractionation of milk, removal of whey fat, etc.

Membrane Preparation

Microfiltration membranes are generally prepared on the basis of classical methods such as phase inversion via various procedures including immersion precipitation, track etching, stretching, etc. Control of membrane morphology is significant for obtaining acceptable permeability, selectivity, and mechanical strength. Permeability reveals the productivity, selectivity exhibits separation capability, and the latter indicates the limitations regarding applied pressure and flowing fluid throughout the membrane.

The parameters affecting the manufacturing process are numerous. Neglecting a part of the influencing factors results in variation in membrane structure and characteristics leading to inconsistency in membrane performance. There is a strong relationship between membrane preparation and membrane properties. Membrane materials (both base and additives) and

Microfiltration Membrane, Fig. 2 Surface of microfiltration membrane showing the tortuous pores

preparation conditions are major concerns. The parameters which must be monitored and controlled during manufacturing process include but not limited to the characteristics of membrane main material, additives and casting solvent,

Microfiltration Membrane, Fig. 3 Cross-section of microfiltration membrane showing thin layer and support

coagulation medium type, precipitation temperature, details of the preparation procedure, and conditions such as temperature (both recipe and environment), pressure, humidity, required time for each step, etc.

Slight manipulating the affecting parameters greatly influences the membrane characteristics. For instance, evaporating the volatile solvent in dope solution before immersing in the coagulation bath improves the membrane structure. Membrane pore size is reduced by increasing the evaporation time. Moreover, the evaporating step is able to prevent the membrane shrinkage in the coagulation bath and suppress the formation of macrovoids leading to mechanical breakdown. It has been shown (Madaeni et al. 2012) that the casting thickness intensively affects the membrane morphology and macrovoid formation. Influence of the coagulation bath temperature and evaporation time on membrane morphology depends on the temperature difference between the coagulation bath and the casting solution (Madaeni et al. 2012).

Although both polymeric and ceramic microfiltration membrane are in use, similar to other types of membranes, polymeric membranes are more common. A widely used polymer for manufacturing microfiltration membranes is

polyvinylidene fluoride (PVDF). This is due to excellent chemical resistance and good thermal and mechanical properties. The polymer is acid resistant, chemically inert, semicrystalline polymer containing crystalline, and amorphous or rubbery phases. Thermal stability and flexibility are provided by the crystalline and the amorphous phases, respectively. PVDF is readily dissolved in many solvents but is stable against corrosive chemicals including acids, alkaline, and oxidants.

Membrane Modification

Microfiltration membranes may be modified after preparation to convert the existing membrane to a new one with enhanced characteristics. Nowadays, this is the main procedure for obtaining superior membranes. The modification techniques are developing and may be considered as a hub for researches in the field of membrane manufacturing. The methods include but not limited to surface treatment (coating, grafting, radiation), functionalization of membranes with appropriate chemical groups, and introduction of nanoparticles into the membrane recipe or onto the membrane surface.

For instance, surface modification of PVDF membrane was conducted using 8-hydroxyquinoline

Microfiltration Membrane,

Fig. 4 Deposition of particles on the surface and inside the pores of microfiltration membrane

(Madaeni and Heidary 2012). The introduced functional group interacts with hydroxyl group of PVDF membrane due to the hydrogen-bond interaction. The interaction is chemically stable. This chelating agent forms sparingly soluble derivatives with metallic ions. The modified membrane can be employed for the removal of cadmium and nickel from water.

Fouling

The main obstacle for application of membranes is fouling. This is due to the deposition of feed components on the membrane surface or in the membrane pores (Fig. 4). The precipitation of particles gradually leads to formation of a cake layer (Fig. 5). Fouling results in flux decline (lower productivity) and rejection alteration (lower selectivity). The most important fouling tackles are characterization, mechanism, and procedures for fouling minimization.

Using cross-flow mode can reduce fouling by deposition limitation on the membrane surface. In addition, the tangential shear depending on the velocity of the suspension is able to remove the foulant layer. The cake deposition on various parts of the membrane is inconsistent. This has been confirmed by SEM micrographs and CFD modeling (Madaeni et al. 2010).

Microfiltration Membrane, Fig. 5 Cake layer formation on the surface of microfiltration membrane

Chemical cleaning is considered as the most important method for regeneration of fouled membrane. The type of cleaning agent depends on the properties of the fouling layer. In many cases the optimum chemical cleaner is elucidated

by trial and error. The choice of cleaning agents is extensive for ceramic membranes.

Microscale Modeling and Membranes

Vasilis Burganos¹ and Eugene Skouras²

¹Institute of Chemical Engineering Sciences, Foundation for Research and Technology – Hellas, FORTH/ICE-HT, Patras, Hellas

²Institute of Chemical Engineering Sciences, Foundation for Research and Technology, Hellas, Patras, Hellas

Microscale modeling refers to the modeling of membrane processes at a resolution level where fundamental phenomena can be described with minimum assumptions using first principles. Modeling tools at the microscopic level usually encompass molecular dynamics (MD) and/or Monte Carlo (MC) techniques, which incorporate many degrees of freedom for the detailed analysis of transport, sorption, reaction, and other process phenomena in membranes. Because of the tremendous significance of the internal structure of

membranes on their performance, especially in separation or preferential transport applications (e.g., fuel cells and membrane reactors), models of the membrane structure at the microscopic level have been developed. In *polymeric*, “rubbery” membranes, models of gas transport in their interior are mainly based on free volume concepts. In the free volume approaches, the concentration dependence of the penetrant diffusivity is described by considering the average spaces between chains (Flory 1969). Such models commonly relate the mutual diffusion coefficients for a gas/polymer system to the free volume of the system. Significant efforts have been made to explain the mechanisms of gas transport in polymers by means of molecular theories. Molecular theories attempt to analyze the diffusion process in terms of specific postulated motions of the polymer chain relative to each other and the motion of penetrant molecules. In order to move into the polymer matrix, the gas molecule pushes the polymer chain and jumps into a new position (Pace and Datyner 1979). At around the glass transition temperature and below, thermal fluctuations of the polymer configurations are limited and penetrants are assumed to jump between cavities with a motion that is likely to entail a significant activation energy barrier (Crank and Park 1968). Simulations in glassy polymers have been attempted with the help of a dual-mode sorption model and some free volume model description. Attempts have also been made to explain gas diffusion in polymers by various molecular mechanisms and models that involve the calculation of the energy for an assumed specific simplified polymer conformation after an energy-activated jump of the penetrant. Most models are leading to the concept of available free volume as diffusing channels (Kotelyanskii and Theodorou 2004). In fact, the mechanism of gas separation by *dense, nonporous membranes* is different from that by porous ones, since diffusion occurs via a *solution-diffusion* mechanism; the permeants dissolve in the membrane material and then diffuse through the membrane down a concentration or chemical potential gradient. Separation between the different permeants is achieved due to differences in the amount of material diffusing through the

membranes. The microstructure of membranes, both polymeric and inorganic, used in *gas separation* is usually reconstructed at the atomistic level, to study the interaction effect of solute or diffusing molecules with the membrane material.

Microscale Modeling and Membranes,
Fig. 1 Atomistic reconstruction of SiO₂ (Accelrys Material Studio)

The reconstruction of *inorganic* membrane structures at the molecular scale is usually realized using MD and MC techniques. Initially, the atoms of the membrane materials are positioned at predefined bulk lattice sites, taken from literature, experimental data, or diffraction techniques. The interatomic potential energy of the configuration is dynamically calculated using some force field description. The force field approach involves an analytical expression that gives the energy of a molecular system in terms of the positions of all its atoms. Both intramolecular (short) and non-bonded (long) atomic interactions are usually taken into account. These data are obtained using either empirical or quantum mechanical (QM) calculations. Using a force field, useful quantities such as momenta, interaction energies, conformational energy barriers, and free energies can be estimated. The atomistic structure is the basis for MD and MC calculations to probe the locations, conformations, and motions of molecules, predicting the actual supply of sorbates to the active sites of membrane (Allen and Tildesley 1987). Mesoscopic and macroscopic membrane process parameters, such as permeabilities, diffusivities, sorption isotherms, reaction and decay coefficients, as well as (perm) selectivities, used in mesoscopic simulations derived from kinetic theory, Fickian, or Stefan-Maxwell (dusty gas) approaches, can then be derived based on proper integration of their microscopic origins (Figs. 1 and 2).

Microsolute

Radoslav Paulen

Department of Biochemical and Chemical Engineering, Technische Universität Dortmund, Dortmund, Germany

Microsolute represents an operational term which denotes any diffusible (able to pass through a membrane) solute(s) in a solution that also contains nondiffusible (retained by membrane) solute(s), macrosolute. Membrane filtration may be used to treat such solution to recover microsolute which is valuable from solution or to filter microsolute which is regarded as impurity out of the solution.

Distinction of species considered as microsolute depends on membrane process which is used to treat the solution (Cheryan 1998), in the case of:

- Microfiltration – Microsolute is represented by macromolecules and species with smaller particle sizes.
- Ultrafiltration – Microsolute represents dissociated acids, divalent salts, sugars, and species with smaller particle sizes.
- Nanofiltration – Undissociated acids and monovalent salts can be recovered or filtered out.
- Reverse osmosis – Only water passes through membrane and thus can be considered as microsolute.

Microwave Synthesis of Zeolite Membranes

Yanshuo Li

State Key Laboratory of Catalysis, Dalian Institute of Chemical Physics, CAS, Dalian, China

Microwave synthesis of zeolite membranes applies microwave irradiation to the synthesis of zeolite membranes as heat source. Microwave technique is regarded as a novel tool in chemical synthesis which offers enhanced speed, reproducibility, and scalability compared to conventional heating. The pioneer work on microwave synthesis of zeolites can be traced back to 1988, and work on zeolite films and membranes subsequently began in the late 1990s. Microwave heating usually combines with two hydrothermal synthesis strategies: in situ synthesis and secondary (seeded) growth. So far, LTA, MFI, AFI, FAU, SOD, T, ETS-4, et al. types of zeolite membranes have been successfully synthesized with the assistant of microwave heating (Li and Yang 2008). LTA zeolite membrane is most extensively studied among them and achieves scale-up to produce commercial zeolite membranes (Xu et al. 2000; Li et al. 2006).

Microwave synthesis of zeolite membranes can have certain benefits over conventional synthesis methods:

1. Shorter synthesis time with higher energy efficiency
2. Uniform crystal size and facile morphology control
3. Improved membrane compactness with higher membrane selectivity
4. Easier for scaling up

It is generally accepted that microwave heating mainly owes its superiority to being instantaneous, volumetric, and selective, known as “thermal effects.” Some researchers suggest the existence of “nonthermal effects,” even in liquids, which are supposed not to require the transfer of microwave energy into thermal energy. For microwave synthesis of zeolite membranes, nonthermal effects are still part of an ongoing debate. Some speculations of the nonthermal effects are proposed for microwave synthesis of LTA zeolite membranes (Li and Yang 2008). In their opinion, the acceleration effect of microwave synthesis is mainly due to the thermal effects, whereas the distinctive morphology of LTA zeolite membranes synthesized by microwave is due to the nonthermal effects.

Milk Fat Hydrolysis

Angela C. Macedo¹ and F. Xavier Malcata²

¹LEPABE – Laboratory of Engineering of Processes, Environment, Biotechnology and Energy, University of Porto, Porto, Portugal

²DEQ – Department of Chemical Engineering and LEPABE – Laboratory of Engineering of Processes, Environment, Biotechnology and Energy, University of Porto, Porto, Portugal

Milk contains ca. 3.4 % total milk fat – which has probably the most complex fatty acid profile of all edible fats. Despite the over 400 individual fatty acid residues identified, only 15–20 account for 90 % of milk fat: saturated

(4:0, 6:0, 8:0, 10:0, 12:0, 14:0, 16:0, and 18:0), monounsaturated (16:1 and 18:1), and polyunsaturated (18:2 and 18:3). Some of these fatty acids are found to be in very low levels, but they are also characterized by very low odor thresholds – so they contribute unique and desirable flavor keynotes.

Milk fat can be degraded chiefly by oxidation upon exposure to light and hydrolysis in the presence of enzymes; these two chemical processes follow quite different chemical mechanisms. Enzymes able to hydrolyze fat are called lipases (or glycerol ester hydrolases, EC 3.1.1.3), and the process is often referred to as lipolysis. These enzymes possess a catalytic triad similar to those in proteases but along evolution have developed a portion of the peptide chain into a lid that covers the active site – which opens (and thus permits access to substrate) only when a water/lipid interface is present; this unique feature makes their action distinct from that of classical esterases in that they are activated by lipids in emulsified form.

Lipases suitable for modification of milk fat – toward incorporation into baked goods and the like – are commercially obtained from a range of sources: milk (lipoprotein lipase), pancreas (pancreatic lipase), molds (e.g., *Aspergillus niger*, *Geotrichum candidum*, and *Penicillium roqueforti*), bacteria (e.g., *Achromobacter lipolyticum* and *Pseudomonas fluorescens*), and the gastrointestinal tract (kid and lamb pregastric esterases). Several genetically engineered microorganisms may also produce such enzymes, both in endogenous and exogenous forms (Fox and McSweeney 1998).

Lipases also have the ability to catalyze the reverse of hydrolysis – i.e., ester synthesis, under microaqueous conditions. These two basic processes may then be combined in a sequential fashion to lead to interesterification reactions. The underlying catalytic mechanism resembles closely natural metabolic pathways, so lipase-based processes are viewed as more environment friendly than typical bulk chemical syntheses. Because of their low activation energies, lipase-mediated processes require mild temperature and

pH, so energy consumption is small and there is little thermal damage to either reactants or products. Owing to their chemical selectivity and stereoselectivity, lipases may generate high added-value products that are not readily available in natural feedstocks.

The essential manufacturing steps of hydrolyzed (or lipolyzed) milk fat include: preparation of condensed milk or butter oil, preparation of standardized lipase system in water, combination of milk fat substrate and lipase system, homogenization to form a stable emulsion (thereby promoting maximum interfacial enzyme activity), incubation at controlled temperature (until a specified degree of hydrolysis has been achieved), pasteurization (to completely inactivate residual lipase), and final standardization, spray drying (or alternative formulation), and packaging.

Controlled enzymatic hydrolysis of milk fat has been a common practice in the dairy industry to produce butter- or cheese-like products and flavor additives (Walstra et al. 1999). The intrinsic composition of lipolyzed milk fat can indeed impart a range of effects on the sensory profiles of foods: at very low addition levels, a sensation of richness is obtained without any detectable acidity; as addition levels increase, the resulting flavors resemble cream or butter; and when addition levels are even higher, the outcome flavor suggests cheese.

Milk Microfiltration

Carla A. M. Portugal

REQUIMTE-LAQV, Chemistry Department,
FCT-Universidade Nova de Lisboa, Campus da
Caparica, Caparica, Portugal

Membrane-based technologies, in particular pressure-driven membrane processes, have been assuming an increased importance in milk and milk whey processing over the last 40 years. Microfiltration (MF) is a membrane separation process that uses porous membranes with average pore diameters within 0.1 and 10 μm . Therefore, MF membranes are capable of retaining particles, cells and large macromolecules (e.g., polymers), finding diverse applications in dairy industry, such as for the removal of bacteria (Ribeiro et al. 2011), whey defatting (Goudédranche et al. 2000) and the production of concentrates enriched in casein micelles.

In alternative to thermal treatment and centrifugation, milk pasteurization can be performed using MF, which also assures an extended milk shelf life (Kosikowski and Mistry 1990; Ribeiro et al. 2011). MF allows for an efficient removal of bacteria from milk, preventing simultaneously the activity of microbial enzymes, which are released by dead cells remaining in milk upon thermal treatment (Saboya and Maubois 2000). Moreover, MF allows milk processing, i.e., pasteurization and clarification in cold conditions, thus avoiding thermal-induced protein aggregation (Beaulieu et al. 1999). Therefore, MF minimizes the inconvenient alteration of texture and the loss of organoleptic and nutritional properties of milk and milk derivatives (Kosikowski and Mistry 1990) that may result from protein aggregation or post-pasteurization enzymatic activity. Proteins are structurally sensitive to heat, forming aggregates, e.g., β -lactoglobulin and k-casein aggregates, at high temperatures (Beaulieu et al. 1999) which may generate the undesirable depletion of these compounds from milk by precipitation or upon centrifugation. In particular, the reduction of casein content is an important drawback in cheese

industry since it retards the rennet coagulation (Singh and Waungana 2001).

Besides cold milk pasteurization, MF potentiates the development of dairy-based products (e.g., cheeses, butters) with diverse and optimized properties (Daufin et al. 2001). Indeed, MF allows the controlled adjustment of milk ingredients through adequate selection of process conditions (e.g., membrane pore size, transmembrane pressure, temperature). Milk pretreatment with MF generates two different process streams: a retentate solution enriched in casein (casein micelles) that may be used in cheese manufacturing for improvement of the coagulation process and a permeate stream, containing a significant concentration of valuable dairy components, such as sugars (e.g., lactose), whey proteins, and bioactive peptides. Whey proteins, such as α -lactalbumin, β -lactoglobulin, lactoferrin, immunoglobulins and growth factors, have important nutraceutical properties and, as well as the bioactive peptides, are relevant ingredients in food and health applications. The recovery of these compounds either as protein whey concentrates (WPC) or isolates (WPI) came along with the development of ultrafiltration (UF) membranes in later 1970s and 1980s. UF allows the fractionation of milk whey into their isolated components or fractions enriched in a specific target protein, allowing their judicious application as enhancers of product quality according to their particular properties.

The use of pressure-driven membrane processes at an industrial scale has been hampered by membrane fouling problems resulting from a time-dependent deposition of solutes at the membrane surface and within the pores. In dairy processing, membrane fouling is mainly attributed to the deposition of particles, like fat globules and cells, and also it is importantly influenced by protein-protein (protein aggregates) or protein-membrane (protein adsorption) interactions (Velasco et al. 2003). In this context, MF may be used for milk whey pretreatment in order to alleviate fouling intensity in UF and NF processes, which may be used for the recovery of milk whey added value compounds and/or for the reduction of the organic charge of the dairy industry

wastewaters. Membrane fouling causes the apparent decrease of membrane average pore size, leading to the reduction of permeate fluxes, the progressive change of membrane selectivity and consequently the production of process streams with undesirable composition. Membrane fouling is intimately dependent on the process hydrodynamic regime, the membrane module design and the physicochemical characteristics of the processing media (Velasco et al. 2003). Therefore, the process productivity and the product quality results from a combined effect of these factors. Optimal solute separation is generally achieved at subcritical transmembrane pressures (TMPs) where membrane-fouling phenomena and flux decline are not observed (Field et al. 1995). However, if purity is not the main process criteria, such as in bacteria removal by MF, then it is preferable to use TMP slightly above the critical value in order to improve permeate fluxes and hence the process productivity. Additionally, long-term process performances are benefited by operation under minimal fouling conditions, which are achievable by using operation strategies involving soft and uniform TMP conditions (Sandblom 1974).

Milk Protein, UF Application of

Carla A. M. Portugal

REQUIMTE-LAQV, Chemistry Department,
FCT-Universidade Nova de Lisboa, Campus da
Caparica, Caparica, Portugal

Milk is composed of a large diversity of proteins with high nutritional value, specific bioactive properties, and physiological functions. Caseins, including α -casein, β -casein, and γ -casein, are the major milk protein components, representing ~80 % of the total milk protein content (Eça and Ferreira 2006). Caseins have low solubility in the aqueous phase, and therefore they are found in micelle form as a colloid component of milk. Besides caseins, milk contains an important amount of water-soluble proteins, the milk whey proteins, composed of β -lactoglobulin (7–12 %), α -lactalbumin (2–5 %), β -lactoglobulin, serum albumin (0.7–1.3 %), immunoglobulins (1.9–3.3 %) and a minority group of proteins with important bioactivity composed of lactoferrin and lactoperoxidase among others (Eça and Ferreira 2006).

Milk whey is the effluent resultant from cheese production mainly comprised of lactose (79 g/L), mineral salts (5.6–8.4 g/L), and whey proteins (8.4 g/L) (Suárez et al. 2006). Whey contains an important organic load (high chemical oxygen demand, COD, values), and therefore it cannot be discarded into the environment without

previous treatment. Moreover, despite being a rich source of nutraceutical compounds with important physiologic functions, its high salinity disallows its use for animal feed purposes. The use of membrane processes has a dual benefit in milk whey treatment; it allows the reduction of the whey COD content towards the production of a clarified waste stream (Balannec et al. 2005) with physicochemical characteristics that fulfill the requirements for its disposal or reuse. Simultaneously, membrane processes allow for a selective recovery of the added value ingredients, such as lactose or proteins, into fractions enriched in a specific(s) compound(s). Nanofiltration (NF) and reverse osmosis (RO) must be used for an efficient removal of mineral salts and sugars (Catarino et al. 2008; Minhalma et al. 2007), whereas protein fractionation is achieved by ultrafiltration (UF) processes (Van Eijndhoven et al. 1995). The development of UF membranes was driven by the emerging interest in a selective recovery of milk proteins envisaging their use as enhancers of specific product properties. UF membrane pore sizes are within the range of protein molecular size, thus varying between 1 and 500 kDa. UF membranes are classified according to their molecular weight cutoff (MWCO), which expresses their ability to reject 95–97 % of compounds with a specific molecular size. The UF fractionation of milk whey proteins into pure solutions of each specific protein is difficult and hampered by the presence of non-uniform membrane pore sizes, by the ability of proteins to permeate through pores with a MWCO smaller than their molecular size, and also by the presence of membrane fouling. Protein permeation through pores narrower than its molecular size is explained by protein structural adaptability to confined spaces and by the protein structural changes potentially induced by the permeation process (Portugal et al. 2008), e.g., due to the shear stress conditions to which proteins may be exposed during permeation or protein-membrane interactions. Additionally, the progressive deposition of proteins at the membrane surface and within the membrane pores – membrane fouling – leads to changes of membrane selectivity and permeability, resulting in alterations of the chemical composition of the

Milk Protein, UF Application of, Table 1

Description and content of the main proteins present in skimmed milk (Adapted from Eça and Ferreira 2006)

	Proteins	Protein content in skimmed milk (%)

	Lactoperoxidase	-

product. Protein transmission is largely influenced by protein-protein (Saksena and Zydney 1997) and protein-membrane interactions. Attractive protein-protein interactions generate the presence of protein aggregates, thus altering their effective molecular size and consequently amplifying protein rejection. High protein-membrane affinity improves protein adsorption at the membrane surface, leading to higher membrane fouling and a higher decline of flux permeation. Therefore, protein transmission can be controlled by suitable adjustment of the physicochemical properties of the processing media, namely, pH and salt concentration (Nystrom et al. 1998; Menon and Zydney 1999), through modulation of attractive and repulsive protein-protein and protein-membrane electrostatic interactions. Protein transmission through UF membranes and membrane selectivity depend crucially on the processing parameters used. High selective separations are promoted by the selection of membrane with adequate pore sizes and by using moderate permeation fluxes. Hence, protein fractionation processes are benefited by operations under controlled permeate flux since it allows for a better control of the permeate flux at subcritical

conditions, thus reducing the membrane fouling potential (Howell et al. 1998; Crespo et al. 1999).

²National School of Chemistry of Montpellier, University of Montpellier, Montpellier, France

Mineralization in water is the complete breakdown of organic substances with the end products being CO₂, H₂O, and nutrients. If organic compounds contain heteroatoms such as nitrogen, chlorine, phosphate, sulfur, etc., the complete mineralization by oxidation will release inorganic ions like ammonium, nitrate, chloride, orthophosphate, and sulfates, respectively. Production of CH₄ can also be considered as part of the mineralization process because it comes up in parallel to the minerals in methanization.

Mineralization can be the result of a biological or chemical oxidative process in which organic substances are converted to inorganic substances. When referring to membranes, measuring mineralization rate is a way to estimate efficiency of catalytic membrane reactors.

The mineralization rate of organic pollutant in water can be measured by total organic carbon

analyzer (TOC) or chemical oxygen demand (COD) with some restrictions. The evolution of total organic carbon (TOC) is then a measure of the extent of mineralization (Rivas et al. 1998).

Electronic and ionic conductivity

A mixed conducting membrane can transport both electrons and ions as shown in the scheme below (Fig. 1); in most cases the ionic conductivity is based on oxygen ions or protons, but in principle also other ions like halogenide or chalcogenide anions are mobile and can be transported. Perovskites with the crystallographic structure ABO₃ (derived from the mineral perovskite CaTiO₃) are a prominent example for a materials class with mixed conductivity: Oxygen ions can be transported via vacancies in the oxygen lattice (denoted as oxygen deficiency δ in the perovskite structure ABO_{3- δ}), and electrons can be transported via redox cycles of the cations if they can occur in different oxidation states (e.g., Feⁿ⁺, Coⁿ⁺, Tiⁿ⁺). The concentration of vacancies in the oxygen lattice can be engineered by bringing cations with a low valency on the position of high-valency cations (Sunarso et al. 2008).

In contrast to mixed conducting membranes, the membranes used in fuel cells for electricity

generation show only ionic conductivity: In the solid oxide fuel cell (SOFC), the membrane material such as $\text{Ce}_{0.8}\text{Gd}_{0.2}\text{O}_{2-8}$ (CGO) shows only oxygen ionic conductivity and no electronic conductivity, and the electrons have to go therefore an outer circuit, whereas the oxygen ions move through the CGO. In the case of the polymer electrolyte membrane (PEM) fuel cell, the membrane material Nafion shows also only proton conductivity (Grotthuss mechanism) but no electronic conductivity, and also here the electrons have to go an outer circuit, whereas the protons can diffuse through the hydrated Nafion pores.

Therefore, mixed conducting materials are often called materials with an inner shortcut

since oxygen ions and electrons or protons and electrons move through the material.

In the scheme below (Fig. 1), the phenomenon of mixed conductivity is illustrated for a perovskite membrane. On the membrane side with a high oxygen partial pressure (e.g., air), molecular oxygen is split at the surface into atoms, the atoms become ionized, and the oxygen ions occupy empty oxygen ion positions in the oxygen lattice (vacancy) and become transported by a diffusion mechanism to the membrane side with a lower oxygen partial pressure (vacuum, sweep gas) where they back-transform into molecular oxygen. For most perovskites, the electronic conductivity is orders of magnitude higher than the ionic one.

Mixed Conducting Membranes, Fig. 1 Schema of oxygen transport through a perovskite membrane with mixed conductivity (copyright Caro, Uni Hannover): Molecular oxygen is split at the membrane side with high oxygen partial pressure (normally air) into atomic oxygen species O^* which are adsorbed at the surface. After ionization, the oxygen ions O^{2-} enter the mixed conducting membrane material. By a diffusional hopping process among the vacancies in the oxygen lattice, the oxygen ions can enter the membrane side facing a low oxygen partial pressure. Here the reverse process takes place: The oxygen ions decompose into atomic surface oxygen O^* and electrons, and the latter diffuse to the air side where they are consumed in the oxygen ionization. The surface oxygen species O^* dimerize and form molecular oxygen which is desorbed into the gas face. To keep the oxygen partial pressure low on the permeate side (driving force for permeation), the molecular oxygen has to be removed by pumping or a sweep gas; it can be also consumed in a chemical oxidation reaction (Shao et al. 2001)

Degree of mixedness

Mixing index is a measure of the degree to which fluid flow will promote the dispersion of dissolved solutes or suspended materials in the fluid, leading to homogeneity. It is an indicator of the quality of the mixing process.

Mixing can be defined as a process that influences a heterogeneous physical system such that it becomes more homogeneous. In fluid systems, mixing leads to heat and/or mass transfer between different locations within the fluid. Mixing is of particular importance at the microscale (from several hundred microns to the nanometer range), where diffusion dominates momentum, heat, and mass transfer (Nam-Trung and Zhigang 2005). Several types of mixing have been identified in fluid systems (Ottino 1989): the mixing of fluids containing dissolved solutes caused by stretching and folding of material, the mixing governed by diffusion and chemical reaction, and the mixing caused by breakup and coalescence of material.

A mixing index can help determine whether mixing is occurring and to what degree. A simple mixing index is the Peclet number (Pe), which is defined as the ratio of convection to diffusion:

$$\text{Pe} = \frac{Ul}{D} \quad (1)$$

where U is the (absolute) fluid velocity, D is the solute diffusivity, and l is a relevant length scale. A possible length scale is the Prandtl length (Plawsky 2001), which is the length of the path a mass of fluid or eddy would travel before losing its individuality by mixing or coalescing with its neighbors. A large Peclet number means convection dominates and more mixing is taking place.

Studies of mixing strategies often evaluate the extent of mixing enhancement which is produced in addition to the mixing intrinsic to the original flow field. For this purpose, it is common to use the perturbation velocity vector $\mathbf{u}$, rather than the absolute velocity $\mathbf{U}$, to quantify mixing. The kinetic energy of the perturbation, referred to as the “turbulent kinetic energy” (κ), is a simple measure of mixing:

$$\kappa = \frac{1}{2} \int_{\Omega} \|\mathbf{u}\|_F^2 dV \quad (2)$$

where Ω is the volume of fluid under analysis and $\|\mathbf{u}\|_F$ is the Frobenius norm of the perturbation velocity vector. However, kinetic energy itself is not sufficient for effective mixing. Mixing caused by material stretching and folding can be quantified through the stretching length based on the gradient of perturbation velocity (Ottino 1989):

$$S = \int_{\Omega} \|\Phi\|_F^2 dV \quad (3)$$

where $\Phi = [\nabla \mathbf{u} + (\nabla \mathbf{u})^T]/2$ is the stretching tensor. A mixing estimation parameter that uses the vorticity to describe mixing induced by vortices can also be defined (Alexiadis et al. 2007). Defining $\Psi = [\nabla \mathbf{u} - (\nabla \mathbf{u})^T]/2$ as the folding tensor, mixing related to folding can be quantified through

$$\mathcal{F} = \int_{\Omega} \|\Psi\|_F^2 dV \quad (4)$$

The sum of perturbation-induced stretching and folding can also be used as a mixing index (Balogh et al. 2005; Ouyang et al. 2013) and is expressed as

$$\mathcal{M} = S + \mathcal{F} = \int_{\Omega} \|\nabla \mathbf{u}\|_F^2 dV \quad (5)$$

The mixing indices defined by Eqs. 3, 4, and 5 describe mixing enhancement due to perturbations but do not reflect mixing inherent in the steady-state system and related to the original velocity gradients and momentum diffusion. The interaction between steady-state flow and the perturbation can also lead to stretching and is described by

$$\Gamma = \int_{\Omega} \{(\mathbf{U} \cdot \nabla) \mathbf{u} + (\mathbf{u} \cdot \nabla) \mathbf{U}\} \cdot \mathbf{u} dV \quad (6)$$

Mixing indices have also been used in the design of control systems that maximize the degree of mixing. Expressions involving turbulent kinetic energy and a measure of spatial gradients of perturbation velocities have been used as cost

Mixing Index, Fig. 1 Examples of mixing caused by flow instabilities in a spacer-filled channel

functionals for optimal flow control problems (Aamo and Krstić 2003). Maximizing these cost functionals leads to mixing enhancement. This has applications for membrane separation systems (Ouyang et al. 2013), as mixing enhancement within the vicinity of the membrane surface leads to an increase in the throughput of the membrane system (Fimbres-Weihs and Wiley 2008).

In membrane systems, mixing can be caused by mechanical inserts, by laminar flow instabilities such as oscillating flow or eddy flow, or by turbulent flow (Winzeler and Belfort 1993). Instabilities can be promoted through flow obstacles (eddy promoters) such as the spacers that keep membrane leaves apart, membrane surface modifications, rotating membranes (Couette flow), curved channels (Dean vortices), pulsating flow, and electroosmotic flow. Figure 1 shows examples of flow instabilities caused by spacer mesh filaments in a membrane channel. At the lower Reynolds number of 525, the stationary recirculation region causes mixing behind the spacer filament, but this leads to accumulation of solute within the recirculation region and, hence, poor mixing. At the higher Reynolds number of 840, vortex shedding occurs, leading to more fluid stretching and folding and therefore better mixing within the channel.

Mobile Carrier

Gerardo León

Departamento de Ingeniería Química y
Ambiental, Universidad Politécnica de Cartagena,
Cartagena, Spain

Mobile site carrier. Solute transport and selectivity in liquid membranes is enhanced by the use of compounds, known as carriers, which reversibly react with the specie to be separated, facilitating its transport (carrier-mediated transport). Although the use of fixed carriers has been described (Lacan et al. 1995), mobile carriers are more frequently employed. Fixed carrier technique implies binding the carrier within the membrane solid matrix, either by electrostatic forces, as in the case of ion-exchange membranes as supports or by covalent linkages, so that the

reversible reaction between the solute and carrier occurs continuously throughout the thickness of the membrane. The carrier agents have no mobility within the film, but the solute moves between carrier sites.

Mobile carrier technique implies adding to the liquid membrane phase a compound (mobile carrier), soluble in the membrane phase but insoluble in the feed and product phases, which reversibly reacts with the solute giving a membrane soluble specie. The mobile carrier diffuses from the bulk membrane phase to the feed membrane interface, where it reacts with the specie to be transported. The formed compound diffuses through the membrane to the membrane product interface where, by reversing the described reaction, the transported specie is released into the product phase. The carrier is regenerated, beginning a new separation cycle. In this way, each carrier molecule is able to transport target specie molecules as many times as necessary, so that only a

Mobile Carrier, Fig. 1 Chemical structures and names of different mobile carriers

small amount of carrier is required in the membrane phase even for achieving a high degree of separation. An ideal carrier will possess the following characteristics (Klassen et al. 2005; Kislik 2010):

- high affinity and selectivity for the component to be removed from the feed solution;
- high ability to join to the specie to be removed in the feed/membrane interface (high joining or complexation constant) and high ability to de-join in the membrane/product interface (high de-joining or de-complexation constant);
- rapid kinetics of joining (complexation) and de-joining (de-complexation);
- rapid kinetics of diffusion of the target specie-carrier compound (complex) through the membrane phase;
- formation of a solute-carrier complex that is soluble in the organic solvent; • low solubility in feed and product phases;
- low toxicity and low corrosivity;
- suitable physical properties as density, viscosity, surface tension, etc.;
- easily reused or regenerated;
- no side reactions;
- no irreversible or degradation reactions;
- good chemical stability;
- reasonable price at industrial applications.

Carriers can be classified into three general classes (Ho and Li 1992): acid, basic, and neutral. Acid carriers include chelating compounds (ketoximes, aldioximes, and their mixtures, and β -diketones) and nonchelating compounds (derivatives of phosphorous acids and thioacids, including phosphoric, phosphonic, and phosphinic acids and thioacids and organic acids, such as naphthenic acids). Basic carriers include high molecular weight primary and secondary amines, tertiary amines, and quaternary ammonium salts. Neutral carriers include calixarene derivatives, crown ether derivatives, phosphate and phosphonic esters, and phosphine oxides and sulfides. Chemical structure and names of some of these carriers are included in Fig. 1.

Modeling of Biocatalytic Membrane Reactor

► [Biocatalytic Membrane Reactor, Mass Transport in](#)

Modified Cellophane Membrane

M. S. Mohy Eldin
Polymer Materials Research Department,
Advanced Technologies and New Materials
Research Institute (ATNMRI), City for Scientific
Research and Technology Applications (CSRTA),
New Borg El-Arab City, Alexandria, Egypt

Modified cellophane membrane has been obtained through different modification strategies focused on the alternation of the physical and/or chemical characters and structure to have more controlled pore size and shape for final different applications. Craig and Konigsberg (1961) modified cellophane dialysis membrane through mechanical stretching of wet membrane. Such modification will endorse membranes to permeate those solutes which would barely diffuse through native one to pass through at a much accelerated rate. Peterson and Livingston (1964) cross-linked cellophane membrane chemically using starch

dialdehyde to control permeability of potassium chloride ions from dilute solution. Recently, de Lara et al. (2006) have cross-linked cellophane membranes with different cellulose content using gamma irradiation. They found a decrease in diffusional permeability, but slightly effects on the transport of ions across the membrane as a result of a more tight structure. Weber and Nose (1968) modified the cellophane membrane through fiber reinforcement. They found that the reinforced cellophane membrane had superior physical strength, but was inferior to the regular cellophane membrane in urea clearance. Baldwin et al. (1965), Takigami et al. (1979), Nonaka et al. (1997), and Mohy eldin et al. (2009, 2011) investigated the grafting of cellophane membranes with different types of polymers to have functional cellophane membranes for different applications such as ionic barrier for battery, poly-electrolyte fuel cell, hemodialysis, and immobilized metal ion affinity membranes for protein separation. Tomé et al. (2011) modified cellophane membranes' hydrophobic character and barrier effects by controlled heterogeneous esterification with fatty acid derivatives. A decrease in both the water permeation and the permeability toward definite gases in the wet state was observed for the modified membranes.

Modified Cellulose

Hongyang Ma, Benjamin S. Hsiao and Benjamin Chu
Department of Chemistry, Stony Brook University, Stony Brook, NY, USA

Modified cellulose refers to chemical modifications of mainly hydroxyl groups in the cellulose backbone. There are primary and secondary hydroxyl groups in each cellulose unit, where the C6-hydroxyl group, being the primary one, exhibits higher reactivity. Typical reactions of hydroxyl groups in cellulose, including oxidation, esterification, etherification, urethanization, amidation, and non-covalent modifications (Habibi 2014), are shown in Fig. 1.

There are two approaches to modify cellulose for membrane preparation: homogeneous and heterogeneous. A well-known membrane prepared from homogeneously modified cellulose is the cellulose acetate-based reverse osmosis membrane, fabricated by the phase inversion method (Strathmann et al. 1971). Cellulose esters, including nitrocellulose, have also been employed to fabricate commercially available microfiltration membranes by using the phase inversion method

Modified Cellulose, Fig. 1 Chemical modifications of cellulose for membrane science and technology

M

for drinking water purification (Ulbricht 2006). The goals for homogeneous modification of cellulose are to adjust the properties of cellulose for specific applications. However, cellulose cannot be dissolved in common organic solvents. Thus, ionic liquids have been used to dissolve cellulose, thereby expanding the family of homogeneously modified cellulose for membrane fabrication (Ma et al. 2010). Nevertheless, heterogeneous modification of cellulose has, so far, been more frequently used. As an example, cellulose nanofibers extracted from natural cellulose with a heterogeneous oxidation reaction followed by mechanical treatment (Isogai et al. 2011) can afford viable surface modifications. The surface of cellulose nanofibers with a nanoscaled diameter is covered with hydroxyl, carboxylate, and aldehyde groups which can be further modified following the above strategy. Cross-linked cellulose nanofibers with functional surfaces have been used as a barrier layer in micro- and ultrafiltration

membranes for water purification to remove contaminants. These membranes showed superior filtration efficiency when compared with commercial membranes (Ma et al. 2011).

Modified Fouling Index (MFI)

► Fouling Index

Modularity

Adele Brunetti

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The modularity takes into account the changes of the plant size due to variations of the plant productivity (Criscuoli and Drioli 2007). It is a typical property of membrane operations, since it is possible to add modules, also without having foreseen the expansion of the system in the system design phase.

To compare the modularity of membranes with that of traditional units, a modularity index is defined. Given a variation of the plant productivity (e.g., from productivity₁ to productivity₂), this metric compares the variations of the area (for membranes) with those of the volume (for conventional systems). The membrane system has a higher modularity if the modularity metric is lower than 1; modularity values higher than 1 are in favor of the traditional system.

$$\text{Modularity} = \frac{\left[\frac{\text{Membrane area}_2}{\text{Membrane area}_1} - \frac{\text{Productivity}_2}{\text{Productivity}_1} \right]}{\left[\frac{\text{Conventional unit volume}_2}{\text{Conventional unit volume}_1} - \frac{\text{Productivity}_2}{\text{Productivity}_1} \right]}$$

Molecular Dynamics in Membranes

Elena Tocci

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Over the last 30 years, detailed atomistic molecular modeling techniques, namely, the molecular dynamics (MD) and the Monte Carlo (MC), have become a widely used method for the investigation of the molecular structure of membrane materials and transport properties in various membrane operations (Binder 1995; Gubbins and Moore 2010; Hofmann and Tocci 2009; Maginn and Elliot 2010; Theodorou 2006, 2010; Razmus and Hall 1991; Harmandaris and Mavrantzas 2004).

Molecular dynamics simulations have been used to build or modify membranes and to investigate the physical and surface properties of membranes used in gas separation and water treatment processes. The molecular modeling of polymer-based membrane materials generally starts with the construction of typically rectangular packing models (Hofmann and Tocci 2009). There, the related chain segments of the respective polymer are arranged in a realistic, that is, statistically possible, way. The limited lateral dimensions of packing models of just several nanometers make it impossible to simulate complete membranes or other polymer-based samples. Therefore, on the one hand, bulk models are considered that are typically cubic volume elements of a few nanometers side length that represent a part cut out of the interior of a polymer membrane. On the other hand, interface models are utilized, for example, for the interface between a liquid feed mixture and a membrane surface or between a membrane surface and an inorganic filler. The quality of

atomistic packing models is typically validated via comparisons between measured and simulated properties like wide-angle X-ray scattering (WAXS) curves, densities, etc.

Example: Free-Volume Distribution

The free-volume distribution in amorphous polymers is of paramount importance for their transport behavior toward small- and medium-sized penetrant molecules. Atomistic molecular modeling utilizing bulk models on the other hand can provide additional even more detailed information on the magnitude, the spatial distribution, and the connectivity of accessible volume within an amorphous polymer matrix (Theodorou 2010).

The accessible volume for a given penetrant molecule is the volume of the volume domain composed of points that can be occupied by the center of mass of the penetrant without any overlap between the van der Waals spheres of the penetrant and those of the polymer atoms. For most polymer–penetrant pairs of practical interest, the accessible volume in any configuration is partitioned into disjoint clusters.

Generally, for polymeric membranes with low permeability of small molecules, such as diisopropylidimethyl PEEK WC (DIDMPEEK), the accessible free volume is organized in relatively small isolated holes and a size distribution that is monomodal and extending only to hole radii of about 5 Å (Hofmann and Tocci 2009).

Polymers with ultrahigh permeability, such as PTMSP and Teflon AF2400 of DuPont ($\text{PO}_2 = 1,140$ Barrer), show ultrahigh free volume. In this case, simulation data support the existence of a bimodal distribution of accessible volume clusters. One mode of the distribution, with a maximum at around 3–4 Å, is comparable to the distributions encountered in dense glassy, low permeability polymers. The other, in parallel, is a partly continuous phase of much larger holes that in this case are visible as a peak between 15 and 20 Å (Hofmann and Tocci 2009; Jansen et al. 2009).

Examples in Gas Separation: Dense Polymeric Membranes

The permeation of small molecules in amorphous polymers is typically following the solution diffusion model, that is, the permeability P_i of a feed component i can be envisioned as the product of the respective solubility S_i and constant of diffusion D_i . Both parameters can be obtained experimentally and in principle also by atomistic simulations (Theodorou 2006).

The most common approach to obtain diffusion coefficients for gases and vapors is equilibrium molecular dynamics. The diffusion coefficient that is obtained is a self-diffusion coefficient by using the Einstein (Eq. 1) or by means of the Green-Kubo (Eq. 2) formulations:

$$D = \lim_{t \rightarrow \infty} \frac{\langle [r(0) - r(t)]^2 \rangle}{6t} \quad (1)$$

$$D = \frac{1}{3} \int_0^\infty \langle v(0) \cdot v(t) \rangle dt \quad (2)$$

As temperature is reduced toward and below T_g , penetrant diffusion in an amorphous polymer matrix becomes too slow to be predictable by MD simulations. Direct MD would require long simulation times for the prediction of diffusivity in low-temperature rubbery polymers and polymer glasses, which are most relevant from the point of view of membrane and barrier material applications (Theodorou 2006; Fried 2006). In such cases diffusion is considered as a sequence of infrequent penetrant jumps, and the transition state theory (TST) of Gusev et al. (1995) and the multidimensional TST approach developed by (Greenfield 2004) can be utilized. Transport-related diffusion coefficients are less frequently studied by simulation but several approaches using non-equilibrium MD (NEMD) simulation have also been used (Theodorou 2006).

The solubility of gases and vapors can be obtained by means of several computational approaches, principally the Widom particle insertion (Widom 1963) and the Grand Canonical

Monte Carlo (GCMC) (Binder 1995; Theodorou 2006; Razmus and Hall 1991) methods. The interaction energy of a gas particle inserted within the accessible free volume of the polymer matrix is calculated, and the excess thermodynamic potential μ_{excess} can be estimated from (Eq. 3)

$$\mu_{\text{excess}} = RT \ln \langle \exp(-E_{\text{int}}/kT) \rangle \quad (3)$$

The solubility S is then obtained from relation (Eq. 4)

$$S = \exp(-\mu_{\text{excess}}/RT) \quad (4)$$

Also in this case, another approach is the transition state theory (TST) of Gusev et al. (1995).

The simulations of the sorption and diffusion of low molecular weight penetrants on amorphous polymers have covered a range of different polymers with varieties of chemical complexities ranging from flexible polymers with simple chemical structure, like poly(dimethylsiloxane) (PDMS) (Hofmann et al. 2000), poly(isobutylene) (PIB) (Hofmann et al. 2000), polyethylene (PE) (Hofmann et al. 2000), and polypropylene (PP) (Hofmann et al. 2000), to stiff polymers with detailed chemical structure, like polyamides (Heuchel et al. 2004), PIMs (Larsen et al. 2011), TR-PBO (Park et al. 2014) membranes, and on polyelectrolytes (Dobrynin 2004).

The predicted self-diffusion coefficients depend principally on the quality of the force fields used to model the interactions not only between the penetrant and polymer matrix but also by intramolecular interactions between polymer chains. MD simulation of gas diffusion in polymer membranes generates a wealth of information on the mechanism of gas transport but its use is limited to high free-volume rubber matrices and small gas molecules due to prohibitive CPU times for diffusion coefficients smaller than $10^{-8} \text{ cm}^2 \text{ s}^{-1}$. For this reason, today, the technique is not adequate for systematic screening of a large number of polymer candidates and generating data to be used in a materials design approach.

The slowness of MD is an obstacle to the study of polymer properties, but not a barrier. This is especially true when the properties of interest are localized, as in the case of glass transition or diffusivity of small molecules through a polymer matrix. At the far end of what can be achieved, MD can also be applied to study polymer dynamics on the time and length scales of polymer entanglement. For current applications, we focus on methods that have been illustrated with several polymers and are on the verge of being competitive with existing empirical methods.

Molecular Recognition

Laura Donato

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Molecular recognition is a biological phenomenon which realizes special recognition at molecular level in living and chemical systems. The origin of the process lies in the intrinsic capacity of biomolecules to distinguish between other

compounds and interact with them on the base of their molecular complementarities.

The concept of molecular recognition was introduced by the Nobel Prize Emil Fischer who proposed the “lock and key” model to explain the high specificity of an enzyme for its substrate. According to this model, the enzyme and the substrate possess exactly complementary geometric shape that allows them to perfectly join the one with the other (Fisher 1894). Also for the enzyme-substrate interaction, molecular recognition is also the core of other important biological activities such as antigen-antibody binding and DNA duplication and transcription.

The process is characterized by the onset of specific non-covalent bonding between the interacting molecules. A more modern proposed recognition mechanism called “induced fit” postulated that interacting molecules are flexible and during the recognition process changes of their tri-dimensional structure can be mutually induced (Bosshard 2001). The mutually induced fit mechanism was experimentally proved for many protein-ligand interactions (Wang et al. 2013).

The different postulated recognition mechanisms allow to distinguish static and dynamic molecular recognition. The static recognition, based on the lock and key model, is established between a single guest molecule and a single host binding site. “The dynamic molecular recognition,” which reflects the “induced” fit model, implies the presence of at least two guest molecules. The interaction of the first guest with the first binding site determines conformational change which promotes the binding of the second guest to the second binding site.

A schematic representation of static and dynamic molecular recognition is reported in Fig. 1.

The most important factors driving the molecular recognition are the shape of the interacting molecules, van der Waals attraction forces between them, hydrogen bonding, hydrophobic forces, and electrostatic and electromagnetic effects.

Molecular recognition phenomenon occurring in biological systems inspired numerous studies in

Molecular Recognition, Fig. 1 Static (a) and dynamic (b) molecular recognition

organic chemistry allowing the development of man-made biomimetic recognition materials.

Nominal molecular weight cutoff (NMWCO)

Molecular weight cutoff (MWCO) or nominal molecular weight cutoff (NMWCO) is defined as the minimum molecular weight of a solute that is 90 % retained by the membrane (Drioli and Giorno 2010). MWCO or NMWCO is determined by evaluating the retention of the membrane for components of different molecular weights as plotted in Fig. 1 (Strathmann et al. 2006). The cutoff curve should be as sharp as possible for practical applications (Strathmann et al. 2006).

Test conditions, such as applied pressure, concentration, temperature, etc., influence greatly the results, but no standardized experimental method is currently available. However, it is recommended to use a transmembrane pressure of 100 kPa, a feed concentration of 0.1 %, and a test temperature of 25 °C and high agitation (Cheryan 1998; Strathmann et al. 2006). Several compounds with different molecular weights are often being used in MWCO determination such as polyethylene glycols, dextran, etc. (Cheryan 1998).

In Table 1, a few examples of commercial UF membranes have been given. An example of MWCO given by the manufacture can be 10 kDa; thus the membrane retains molecules with a molecular weight larger than 10 kDa which could be some proteins. However, for real applications, it will depend on the objective of the filtration process, e.g., separation of proteins from salts, the more challenging protein-protein separation, etc. The final

Molecularly Imprinted Membranes

Laura Donato

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Molecularly imprinted membranes (MIMs) are biomimetic materials which have molecular recognition capacity. Thanks to the presence of specific molecular recognition sites in their matrix, these advanced functional membranes are able to discriminate between a molecule of particular interest named “template” and other analytes. The specific recognition is due to the chemical and spatial complementary existing between the template and the recognition sites of the membrane. Molecularly imprinted membranes are identified as a special format of imprinted polymers, and their development is due to the combination of the bioinspired imprinting technique and the oldest membrane science. Exploiting the advantages of both technologies, the development of such systems has made a significant contribution to the improvement of detection and separation processes at the molecular level. In comparison with the traditional application of imprinted polymers, processes based on imprinted membranes are more efficient due to possibility of operate in continuous, without additives, and at low temperature, thus reducing the operating costs. In addition, the specificity of an imprinted membrane is enhanced with respect to a traditional membrane, but in the meantime the separation efficiency is preserved.

Two different transport mechanisms are known: *facilitated permeation* and *retarded permeation*. In the first case, the transport of the template through the membrane is more rapid than the transport of other compounds. The reason of this behavior is due to the presence of a preferential pathway for the template in the membrane which is formed via binding to and dissociating from neighbored recognition sites, thus facilitating its permeation. On the contrary, other solutes are subjected to the slow nonspecific transport. The second transport mechanism is characterized by a retarded permeation of

the template through the membrane, owing to the affinity binding with the recognition sites distributed in the membrane matrix.

The most commonly developed molecularly imprinted membranes have flat-sheet configuration and are prepared via the phase inversion technique from a viscous solution of the membrane-forming polymer which contains also template molecules. The molecular memory of the template is induced in the membrane at the same time as the membrane is forming from its polymer solution. Membranes having hollow-fiber configuration are also prepared using the same technique. Thanks to their high specificity, MIMs are useful for molecular recognition of a variety of substances in food, environmental, and pharmaceutical fields. Most relevant applications are enantiomeric separations (Noaman and Park 2008), purification of drugs (Trotta et al. 2007), enrichment of food additives (Donato et al. 2010), decontamination of water (Sergeyeva et al. 2008), and many others. Imprinted membranes having catalytic properties (Kalim et al. 2005) or useful for specific recognition in organic environment (Del Blanco et al. 2012) also attract the attention of the scientists.

Monitoring NOM-Based Fouling

Raymond L. Legge

Department of Chemical Engineering, University of Waterloo, Waterloo, ON, Canada

Definition

Monitoring of NOM or natural organic matter-based membrane fouling refers to identifying exclusively the NOM components that contribute to membrane fouling in drinking water production. This may be of interest for various reasons including to better understand from a fundamental perspective what contributes to fouling, to implement strategies to mitigate fouling, or to control and optimize the filtration processes.

Overview

The objective of monitoring NOM-based membrane fouling will impact the method of choice for monitoring. A variety of water matrix characterization techniques exist that have as their basis the experimental analysis of NOM, and which may require fractionation of the NOM into its various components prior to some form of detection. NOM constituents can be characterized based on their hydrophobicity and their molecular weight. Among the techniques that involve separation is liquid chromatography/organic carbon detection (LC-OCD), which most commonly involves the use of size exclusion chromatography or SEC. In order to obtain information on the structural and functional characteristics without separation, more sophisticated analytical approaches may be required that rely on different spectroscopic approaches. This may include nuclear magnetic resonance (NMR), infrared spectroscopy (IR), Fourier transform infrared spectroscopy (FTIR), or fluorescence excitation-emission matrices (FEEM). A comprehensive review of the methods that can be used for characterization of NOM will be found in the review by Matilainen et al. (2011). When the objective is to control the fouling

process, it is advantageous to have on-line approaches that provide real-time updates. This is normally not feasible with techniques that rely on separation of the components for analysis. Among techniques that can be employed in this manner are the spectroscopic-based approaches.

Monolithic Membranes

Jordi Llorca

Institute of Energy Technologies, Universitat Politècnica de Catalunya, Barcelona, Spain

Synonyms

[Honeycomb membrane](#); [Structured membrane](#)

Membranes are usually configured in three ways: (i) as long cylinders such as hollow fibers, capillaries, or tubes, (ii) as sheets which are either rolled up or maintained in a flat condition, and (iii) as various monolithic designs with a plurality of cylindrical, flower-like, or honeycomb-like channels (Fig. 1). Channels can vary in diameter and can be present in multiple numbers. Each channel is coated with a membrane layer.

The body of most monolithic membranes is made up of ceramic inorganic materials with macropores (>50 nm), such as alumina, zirconia, titania, or silicon carbide, supporting a multilayer

Monolithic Membranes, Fig. 1 Drawing of an element of a ceramic monolithic membrane. Channels are coated with a membrane layer, which is usually constituted by a first macroporous layer strongly anchored to the ceramic

body, a second mesoporous layer that acts as binder and a third microporous layer, which mainly determines the separation characteristics of the membrane

porous structure exhibiting a non-deformable porosity (Hsieh 1991). Usually, each channel is coated with a membrane layer comprising a first macroporous layer disposed directly on the surface of each channel, a second mesoporous intermediate layer disposed on the first macroporous layer, and a third microporous layer (micropores < 2 nm) disposed on the second mesoporous intermediate layer. The membrane layers are normally sintered in place, making an extremely strong ceramic-to-ceramic bond with the monolithic membrane body. Synthetic and modified natural polymeric materials are also being used and, more recently, monolithic membranes containing carbon fibers with great mechanical strength (enabling to withstand working pressures greater than 50 bars).

Ceramic monolithic membranes offer significant advantages over other types of membranes in many applications operating under extreme conditions because of their intrinsic properties, i.e., rigid porous structure, high-temperature resistance, high-chemical resistance to aggressive aqueous and organic media, and insensitiveness to biological attack. These applications typically are the treatment of waste liquids and gases, liquid processing including drinking water and separation of biomolecules, and product recovery in industry.

For liquid filtration, existing monolith membranes use a cross-flow filtration configuration in

which a single feed stream that enters the filtration channels of a ceramic membrane element is divided into a permeate (solution that passes through the membrane and exits transverse to the monolith flow path) and a retentate (solution that is retained by the membrane and exits parallel to the monolith flow path and is recycled back into the feed stream). The separation is driven by the pressure difference from one side of the membrane to the other, commonly referred to as transmembrane pressure. The parallel flow of the feed stream, combined with the boundary layer turbulence created by the cross-flow velocity, continually sweeps away particles and other substances that would otherwise build up on the membrane surface (Lee 2011). For gas separation, it is often advantageous to use two discrete feed streams in which one of the feed streams is a sweep gas to keep permeate concentration low to maximize the driving force for separation. This requires two discrete flow paths in fluid communication only through the porous walls of the monolith structure.

According to the application, the membrane elements can be also tailored with appropriate active surfaces, such as catalysts, resulting in the so-called catalytic monolithic membranes. They have been used in industry for a variety of coupling reactions (hydrogenation, dimerization, etc.), although their drawback is the small catalytic surface area per unit volume of the reactor.

Monolithic Reactor

Jordi Llorca
Institute of Energy Technologies, Universitat
Politécnica de Catalunya, Barcelona, Spain

Synonyms

[Structured reactor](#)

Monoliths are structures that contain various types of interconnected or separated channels (straight, wavy, or crimped) in a single block of material (e.g., honeycombs, foams, or interconnected fibers). Most monolith reactors consist of one piece of ceramic material. This ceramic block contains a large number of parallel channels extending over the entire length of the

block, separated by thin walls. The channels normally have circular, square, or triangular cross sections but also channel geometries produced by wrapping up flat metal sheets with corrugated metal sheets in between (Fig. 1). Monolithic reactors are those filled with monoliths that are either made of porous catalytic material or the catalytic material is deposited (washcoated) in the channels of an inert monolithic support (Avila 2005). In both arrangements, the channel walls function as catalyst and the channels provide space for flow of gas and/or liquid. Another type of monolithic reactors are those where the thin walls act directly as membranes or are used as a substrate for depositing materials that serve as membranes for separation and/or purification purposes.

Currently, ceramic and metallic monoliths are the two major types of monolith supports used. Ceramic monoliths are mostly prepared by extrusion while metallic monoliths are normally made by corrugation. The ceramic material cordierite (magnesium aluminum silicate) is commonly used because it is cheap, it can be easily manufactured with high porosity, and it has a very small thermal expansion coefficient (Cybulski 1998). Channel size and shape affect the pressure drop across the channel and the hydrodynamics of the fluid phases. The monolith themselves have a square, oval, racetrack, or round geometry, depending on the application. Larger volumes of monolith structures are obtained by stacking smaller building blocks.

Monolithic Reactor, Fig. 1 400 cpsi cordierite monolith before (*left*) and after (*middle*) catalyst deposition and 1200 cpsi metallic monolith (*right*)

Monolithic Reactor, Fig. 2 Transversal section of a square-channel monolith with the parameters employed to characterize the monolith geometry

Different types of distributors can be used to achieve the desired uniform flow distribution over the monolith cross section, such as spray nozzles, shower heads, hole plates, glass frits, and static mixers.

In the case of the square-channel monoliths, the monolith geometry is fully defined by two parameters: the channel size or repeat distance (L), and either the wall thickness (w , usually between 0.06 and 0.5 mm) or cell density (N), which is defined as number of cells per square inch (cpsi) and typically ranges between 100 and 1200 (Fig. 2). Other parameters commonly used to characterize the monolith structure are the void fraction, which varies between 0.5 and 0.9 and is frequently expressed as the open frontal area (OPA), the geometric surface area (GSA), and the surface-to-volume ratio (Williams 2001).

Monolithic reactors have some common features in most of the applications for which they are used. Compared with other types of reactors commonly used in industry they have numerous advantages, such as low pressure drop, especially under high fluid throughputs; high specific

external surface area for mass transfer; elimination of internal diffusion limitations when thin walls are used; low axial dispersion and back-mixing, and therefore high product selectivity; reduction of fouling and plugging, and thus extended lifetime; and as a result of the application of a regular structure, the scale-up to industrial relevant size is considerably easier. The main disadvantages are potential low radial heat transfer rate, and thus difficulty in temperature control, especially for ceramic monolith supports.

Monolith reactors were developed for the cleaning of exhaust gases from combustion processes, both in cars and large power plants. For these processes, monolith reactors offer an irresistible combination of low pressure drop and high surface area. Due to their significant advantages over conventional types of reactors, monoliths have also applications in gas phase, gas-liquid phase, liquid phase, or gas-liquid-solid phase reactions in the environmental and chemical, petrochemical, biochemical, and energy industries.

Monovalent Cation Selective Ion-Exchange Membranes

Yoshinobu Tanaka

IEM Research, Ushiki-shi, Ibaraki, Japan

Monovalent cation selective ion-exchange membranes are developed by forming the polycation

Monovalent Cation Selective Ion-Exchange Membranes,

Fig. 1 Polycation layer formed on the cation-exchange membrane. Tanaka and Seno (1981), Fig. 8

layer on the surface of the cation-exchange membrane as illustrated in Fig. 1 for preventing CaSO_4 precipitation in electrodialytic seawater concentration. In the polycation layer, positively charged groups pack closely together, and Coulomb and Born repulsive force exert on surrounding cations. The potential produced by two adjacent polycation groups is illustrated in Fig. 2; under the influence of an electric field, a mobile cation Q moves across the lowest potential barrier between two polycation groups E_1 and E_2 . Any mobile cation must pass over the potential barrier of the polycation layer in order to permeate the membrane. Under these circumstances, the transport of divalent ions across the membrane becomes more difficult than for monovalent ions, because greater energy is required for doubly charged cations to pass over the barrier.

The mechanism of monovalent cation permselectivity increase (divalent ion permeability decrease) is discussed by applying the Boltzmann equation to the potential profile illustrated in Fig. 3 (Tanaka and Seno 1981). In this system, the feed solution contains monovalent

Monovalent Cation Selective Ion-Exchange Membranes, Fig. 2 Potential distribution in the polycation layer. Tanaka and Seno (1981), Fig. 9

cation A and divalent cation B with common anions.

When no polycation layer is formed on the membrane surface, the potential profile is depicted schematically by the dotted line in Fig. 3. Under an applied electric current, the concentration polarization is assumed to be neglected because the boundary layer is diminished due to forced flowing solutions in desalting cells. Thus, the relationship between the ion concentration in the desalted solution and in the membrane is approximately expressed as follows, applying the Boltzmann equation and taking the potential height in the desalted solution phase as standard:

$$\begin{aligned}\bar{C}_A &= C'_A \exp\left(-\frac{\bar{\psi}_A}{RT}\right) \\ \bar{C}_B &= C'_B \exp\left(-\frac{\bar{\psi}_B}{RT}\right)\end{aligned}\quad (1)$$

where $\bar{C}_i$ and C'_i are the concentration of ion i in the membrane and in the desalted solution, respectively. $\bar{\psi}_i$ is the potential height in the membrane for ion i measured from the desalted solution

Monovalent Cation Selective Ion-Exchange Membranes,

Fig. 3 Potential profile across a polycation layer and a cation-exchange membrane. Dotted line shows the profile with no polycation layer. Tanaka and Seno (1981), Fig. 10

phase. The ion fluxes are introduced from Eq. 1 and the potential gradient term in the Nernst-Planck equation as

$$\begin{aligned} J_A^0 &= -z_A \bar{u}_A \bar{C}_A \frac{d\varphi}{dx} = -z_A \bar{u}_A C'_A \frac{d\varphi}{dx} \exp\left(-\frac{\bar{\psi}_A}{RT}\right) \\ J_B^0 &= -z_B \bar{u}_B \bar{C}_B \frac{d\varphi}{dx} = -z_B \bar{u}_B C'_B \frac{d\varphi}{dx} \exp\left(-\frac{\bar{\psi}_B}{RT}\right) \end{aligned} \quad (2)$$

where J_i^0 , z_i , and u_i are the flux, the valence, and the mobility of ion i . $d\varphi/dx$ is the potential gradient in the membrane. The permselectivity coefficient of ion B against ion A; $(T_A^B)^0$ is expressed using Eq. 2 as follows:

$$\begin{aligned} (T_A^B)^0 &= \frac{\left(\frac{z_B J_B^0}{z_A J_A^0}\right)}{\left(\frac{z_B C'_B}{z_A C'_A}\right)} \\ &= \frac{z_B \bar{u}_B}{z_A \bar{u}_A} \exp\left(-\frac{\bar{\psi}_B - \bar{\psi}_A}{RT}\right) \end{aligned} \quad (3)$$

When the polycation layer is formed on the membrane surface, the potential profile is formed

as indicated by the continuous line in Fig. 3. Concentration of ion i in the polycation layer is expressed by

$$\begin{aligned} C_A^* &= C'_A \exp\left(-\frac{\psi_A^*}{RT}\right) \\ C_B^* &= C'_B \exp\left(-\frac{\psi_B^*}{RT}\right) \end{aligned} \quad (4)$$

where C_i^* and ψ_i^* are, respectively, the concentration and the potential height in the polycation layer for ion i .

When the ionic mobility in the membrane phase is rather high, ion concentration in the membrane is primarily controlled by the ratio of uptake of those ions from the solution phase. This situation is observed for the carrier-mediated transport of ions through liquid membranes (Bloch 1970). Since the polycation layer serves as a barrier to ionic transport across the membrane system, and the permeation step through this barrier is rate determining, it is reasonable to suppose that a kinetic-controlled mechanism holds in the present case. Under these conditions, it is

safely considered that the concentration ratio in the membrane, $\bar{C}_A/\bar{C}_B$, is primarily determined by the concentration ratio in the polycation layer, C_A^*/C_B^* . If $\bar{C}_i$ is tentatively assumed to be proportional to C_i^* , then the ion fluxes across the membrane will be given by Eq. 5:

$$\begin{aligned} J_A^0 &= k z_A \bar{u}_A C_A' \frac{d\varphi}{dx} \exp\left(-\frac{\psi_A^*}{RT}\right) \\ &= k J_A^0 \exp\left(-\frac{\psi_A^* - \bar{\psi}_A}{RT}\right) J_B^0 \\ &= k z_B \bar{u}_B C_B' \frac{d\varphi}{dx} \exp\left(-\frac{\psi_B^*}{RT}\right) \\ &= k J_A^0 \exp\left(-\frac{\psi_B^* - \bar{\psi}_B}{RT}\right) \end{aligned} \quad (5)$$

k is the constant. T_A^B is derived from Eq. 5 as follows:

$$\begin{aligned} T_A^B &= \left(\frac{z_B J_A}{z_A J_B}\right) \left(\frac{z_A C_A'}{z_B C_B'}\right) \\ &= \frac{z_B \bar{u}_B}{z_A \bar{u}_A} \exp\left(-\frac{\psi_B^* - \psi_A^*}{RT}\right) \\ &= (T_A^B)^0 \exp\left(-\frac{\psi_B - \psi_A}{RT}\right) \end{aligned} \quad (6)$$

The potential $\psi_i = \psi_i^* - \bar{\psi}_i$ is that of polycation layer relative to that in the membrane phase. The potential difference $\psi_B - \psi_A$ provides a mechanism for the separation of ion A from ion B and can be estimated from the electrodialysis experiment as follows:

$$\begin{aligned} \psi_B - \psi_A &= RT \ln \left[\left(\frac{J_B^0}{J_A^0} \right) / \left(\frac{J_B}{J_A} \right) \right] \\ &= RT \ln \left[(T_A^B)^0 / T_A^B \right] \end{aligned} \quad (7)$$

Monovalent Cation Selective Ion-Exchange Membranes, Table 1 Specifications of the electrodialyzer

Tanaka (1974), Table 1

Specifications of the electrodialyzer are shown in Table 1. The flow sheet of the test apparatus is illustrated in Fig. 4 (Tanaka 1974). Seawater was supplied into each desalting cell at linear velocity of 5 cm/s through a circulation tank, keeping the temperature to 25 °C and applying current density of 4 A/dm². When the salt concentration of the concentrated solution reached a stationary value, polycations (Nonisold, Daiichi Kogyo Pharmaceutical Co. Ltd.) were supplied continuously from the reservoir into the circulation tank to keep its concentration at a constant value. During the electrodialysis, the concentrated solutions

MOR Membrane

► [Mordenite Membrane](#)

Mordenite Membrane

Reyes Mallada

Department of Chemical and Environmental Engineering and Aragon Nanoscience Institute, Universidad de Zaragoza, Zaragoza, Spain

Synonyms

MOR membrane

Mordenite (MOR) is a high-silica zeolite, with a molecular formula $\text{Na}_8(\text{H}_2\text{O})_{24}[\text{Al}_8\text{Si}_{40}\text{O}_{96}]$, in which the Si, Al content of the framework and the cation content of the cavities are moderately variable. The Si/Al ratio could be varied between 4 and 20. MOR-type zeolite consists of 12-Membered Ring (MR = straight channels ($6.5 \times 7.0 \text{ \AA}$) parallel to the c-axis, interconnected to tortuous 8-MR

channels ($2.6 \times 5.7 \text{ \AA}$) in the a-axis, see Fig. 1, (International Zeolite Association commission). Typical morphology of the crystals corresponds to long needles that run along the c axis (see Fig. 2), but other morphologies could be also observed.

Mordenite membranes have been prepared by different methods: the vapor phase transport method, direct (unseeded) hydrothermal synthesis with or without template, and see [Seeded Hydrothermal Synthesis for Zeolite Preparation](#). This last method could be considered as the most convenient in terms of synthesis time reproducibility and is easy to scale up.

The orientation of the zeolite mordenite crystals in the MOR membranes is very important, favoring the transport of the molecules through the big 12MR channels, see Fig. 2. Control of the orientation could be achieved by secondary growth and control of the synthesis gel composition (Li et al. 2003). Figure 3 shows random orientation of zeolite crystals in mordenite membranes, (Navajas et al. 2007).

Due to the relatively big pore size 0.65 nm these membranes have not been tested in separation of small molecules of permanent gases, instead these membranes have been proposed as good candidates in pervaporation separation, (see [Mordenite Membrane in Pervaporation](#)). In particular, due to the relatively high silica to aluminum ration these zeolites are selected for water pervaporation in acidic mixtures, (see [Acetic Acid Dehydration by Pervaporation Zeolite Membranes](#)).

Mordenite Membrane in Pervaporation

Reyes Mallada

Department of Chemical and Environmental Engineering and Aragon Nanoscience Institute, Universidad de Zaragoza, Zaragoza, Spain

Mordenite membranes belong to the inorganic microporous (pores below 2 nm according to IUPAC definition) membrane group. These membranes are applied in gas separation and pervaporation. In the case of mordenite, since the kinetic diameter of most of the permanent gases is bigger than the pore size of this structure 0.7 nm (see entry “► [Mordenite Membrane](#)”), the membranes are not applied in gas separation, and pervaporation is the main application envisioned in the literature. Furthermore the relatively high Si/Al ratio and moderate hydrophilicity make these membranes perfect candidates for dehydration of acidic mixtures by pervaporation (see entry “► [Acetic Acid Dehydration by Pervaporation Zeolite Membranes](#)”).

There are many reported data for pervaporation of water/alcohol mixtures; the performance is lower compared to the more hydrophilic zeolite A membranes (Arruebo et al. 2008). In the separation of a mixture of H₂O/isopropanol, 10% wt/90%wt at 75 °C water fluxes are in the order of 0.1–0.2 kg/hm² in the case of MOR, and in the case of H₂O/isopropanol 10%wt/90%wt at same temperature, values of 2–9 kg/hm² could be found. Thus, the main application of mordenite membranes in pervaporation is in the case of dehydration of acidic mixtures where zeolite A membranes degrade, while MOR membranes remain stable. The economic feasibility of mordenite membranes for pervaporation of acetic acid/water mixtures has been also studied by the researchers of Mitsubishi (Sato et al. 2011). The membrane performance in pervaporation was measured in a feed mixture of water (50 wt%)/AAc (50 wt%) to be 10.9 kg m²/h for permeate flux and to be 0.77×10^{-6} mol m²/sPa for water permeance with separation factor of 500 at 130 °C.

Mosaic Membranes

Karel Friess

Department of Physical Chemistry, University of Chemistry and Technology Prague, Prague, Czech Republic

Synonyms

[Charged mosaic membrane](#); [Ion-exchange mosaic membranes](#)

Mosaic membranes (MM) are composed of macroscopic fixed domains of cation exchange (negatively charged) and anion exchange (positively charged) arranged in parallel resins separated by a neutral polymer or ion-exchange channel matrix (see Fig. 1) (Soellner 1932; Strathmann 2004; Wu et al. 2006). Inside channels with positive charge is higher concentration of negatively charged anions and vice versa. MM are effective in concentrating of diluted electrolytes in the presence of hydrostatic pressure and chemical potential gradient (*piezodialysis*) (Sata 2004). Mosaic membrane can be used also for separation of electrolytes from nonelectrolytes.

MM can be prepared (Sata 2004) by various methods: (i) cross-linking reaction of two different copolymers with ion-exchange resins; (ii) cutting a laminated block of alternating cation-/anion-exchange membranes into films (perpendicular to the membrane surface); (iii) casting (layer-by-layer) a block-copolymer film with one exchange groups, insulating layer, and

Mosaic Membranes, Fig. 1 Schematic draw of structure of mosaic membrane configurations: cation- and anion-exchange domains in neutral matrix (*left*), cation-exchange

domains in anion-exchange matrix (*middle*), and anion-exchange domains in cation-exchange matrix (*right*)

block-copolymer film with opposite exchange groups; (iv) casting of a film using a dispersion containing ion-exchange microsphere gels and polymer.

Alternative approaches of preparation of MM consist in ion-exchange asymmetric membrane with a uniform distribution of counterion-exchange particles in the dense integral skin layer (Linder and Kedem 2001) or in use of hybrid materials containing both positive and negative charges (Liu et al. 2005).

Multi-effect Membrane Distillation

Chunrui Wu

State Key Laboratory of Hollow Fiber Membrane Materials and Membrane Processes, Institute of Biological and Chemical Engineering, Tianjin Polytechnic University, Tianjin, China

Multi-effect membrane distillation (MEMD) is a promising technology that can avoid the disadvantages of single-stage MD process. Generally the gained output ratio (*GOR*) evaluating the performance of the single-stage MD is less than 1. However, the *GOR* of the MEMD process can be 20 from literatures. It is even better than multiple-effect evaporation (MEE) and multistage flash (MSF). The MEMD process can significantly increase the thermal energy efficiency and reduce the cost of equipment. Many researchers are trying their best to study the MEMD technology and find out an appropriate process.

The process of a countercurrent direct contact membrane distillation (DCMD) module and a heat recovery heat exchanger was developed in 1987 (Fane et al. 1987). On this basis, different designs for cascade of cross-flow DCMD were developed by Gilron et al. (2007). They theoretically analyzed the influence of the operating conditions such as brine temperature, distillate temperature, and brine flow rate on the performance of MEMD process. Methodologies were presented to maximize energy recovery and show the cost of the cross-flow DCMD stages. The

results indicated that with the optimum number of cross-flow stages, the distillate cost would be competitive with that of large-scale seawater RO.

The MEMD Processes with DCMD Modules

In 2010, a new design was developed by integrating a countercurrent cascade of cross-flow DCMD and a heat exchanger (Lee et al. 2010). The heat exchanger is filled of solid polymeric hollow fibers. A novel numerical simulator was developed to simulate the performances of this device. And an experiment was operated to demonstrate the numerical model. The numerical simulator predicts that the *GOR* can be 12 when the brine flow rate and distillate flow rate are different.

He et al. presented their research about a series of countercurrent DCMD cascades of two types (He et al. 2012). Two different configurations (Fig. 1) with interstage heating or not were theoretically analyzed. The results show that with interstage heating provided at the top of each stage, the energy recovery is about 60 % and *GOR* may be above 20.

The MEMD Processes with VMD Modules

By replacing the flash chambers of MSF desalination systems with membrane distillation modules, a small-scale and off-grid desalination system (Fig. 2) can be built (Edward et al. 2013). The results of model analysis showed that the multistage vacuum membrane distillation (MSVMD) system can achieve the performance of MSF for the same condition. Additionally, MSVMD has some advantages over MSF, such as operation at lower temperature, the use of low temperature heat sources, and the use of inexpensive polymer materials.

The memsys has developed a novel vacuum multi-effect membrane distillation (V-MEMD) module (Zhao et al. 2013). The V-MEMD process is achieved by many single stages connecting. Every single-stage's structure

includes alternating membrane frames and foil frames for evaporation and condensation. Vacuum enhances the membrane distillation process and solar provides the energy. The results showed that the heating and cooling temperatures are the main factors among the operation conditions affecting flux and energy recovery. Also the optimization of module design shows that the memsys module has great potential in increasing the *GOR*.

The MEMD Processes with AGMD Modules

A method that integrates the heat exchanger network (HEN) into the MD system is presented (Lu and Chen 2012). The schematic diagram of the integrated system of AGMD and HEN is showed in Fig. 3. The waste heat from HEN can be the energy source of the MD process so as to reduce the water cost. The method consists of two steps: first, the stream data is calculated for the MD design; second, HEN design is done. The design results show the optimal multistage MD system that can keep high energy efficiency and improve the productive rate of the system. It also gives the optimal operating conditions and explicit stream data. The cost difference between HENs with and without the MD streams is considered as the partial cost of pure water resulting from the MD process.

A heat recovery technology in AGMD process using a two hollow-fiber-set membrane module has been developed. In the module, the hot brine flows through a porous hydrophobic membrane, the vapor through the wall of the porous hydrophobic membrane is condensed on the wall of dense wall fibers and warms up the cold brine flow. The configuration of MEMD process is presented in Fig. 4, which includes the AGMD module described before and an external heat exchanger. Enrichment experiment of semi-volatile organic acids from aqueous solutions by this MEMD process has been completed (Ban Rui et al. 2012). The influence of operating conditions for the performance of MEMD process has been studied. The *GOR* of this experiment can be 9.84

Multi-effect Membrane Distillation, Fig. 1 Two different modes of obtaining increased recovery by operating with a series of cascades: (a) with interstage brine heating and (b) without interstage brine heating

and the acid rejection rate can be 99.93 %. The results present that the MEMD process can be potentially applied to enriching organic acids from their respective dilute aqueous solutions. Using this MEMD process, Xiaojun Li et al. studied the concentration of aqueous sulfuric acid

solution (Xiaojun Li et al. 2012). The *GOR* value obtained was much higher than that in traditional and other modified membrane distillation processes. The maximum value of *GOR* could reach 11.5. And in a long-term stability test (lasting for more than 30 days), the MEMD

Multi-effect Membrane Distillation, Fig. 2 Multistage vacuum MD (MSVMD) process diagram

Multi-effect Membrane Distillation, Fig. 3 Schematic diagram of the integrated system of AGMD and HEN

modules were kept in good condition, which demonstrated the stability of this MEMD process.

A conception of continuous-effect membrane distillation (CEMD) was proposed in 2013 Yao et al. (2013). The CEMD process based on hollow fiber AGMD module and the MEMD process with an AGMD module are exactly the same. However, the research studied two kinds of CEMD modules made from

different membrane fibers. The influences of operating conditions on the performance of CEMD process have been investigated. Within the studied experimental range, the maximum *GOR* value could reach 13.8. The theoretical model successfully predicted the possible ways to obtain a higher *GOR* value. And the experiment data showed agreement with theoretical conclusions.

Multielectron Redox Catalysts

Ubavka B. Mioč¹, Z. D. Mojović² and D. M. Jovanović²

¹Faculty of Physical Chemistry, University of Belgrade, Belgrade, Republic of Serbia

²Institute of Chemistry, Technology and Metallurgy (I.Ch.T.M.), Center of Catalysis and Chemical Engineering, University of Belgrade, Belgrade, Republic of Serbia

Multielectron redox reactions play a key role in many biological and synthetic catalytic processes. Multielectron redox processes require the use of a catalyst able to store several redox equivalents. A redox catalyst is a substance which can accept or donate several electrons such that each electron is added or removed at approximately the same potential. When fully charged, the catalyst should be capable of driving a multielectron redox reaction in a process with a few intermediate steps (Fendler and Bolton 1986).

Multielectron redox catalysts function through redox potential leveling (Huynh and Meyer 2007). Redox potential leveling is a process where proton-coupled electron transfer leads to

the accumulation of multiple oxidizing equivalents over a low range of potential (Wang et al. 2010). The additional demand on the catalyst is that it must accumulate and use multiple oxidative equivalents at high redox potentials and carry out a difficult, multielectron reaction or reactions without reacting with itself or its surroundings.

The ability of heteropoly acids (HPAs) and their conjugate anions (polyoxometalates) to perform fast reversible multielectron redox transformations under rather mild conditions prompted interest in the systems as electrocatalysts for various inert redox reactions including hydrogen evolution and oxygen reduction. It has been recognized that the partially reduced heteropolyanions of W and Mo provide highly reactive mixed-valence redox centers. However, nearly all multielectron transfer in polyoxometalates systems is driven by either adding strong reducing and oxidizing reagents into solution or through electrochemical redox reactions (Takashima et al. 2012).

Polyoxometalates can undergo fast and reversible multielectron redox reactions. Electron transfer occurs between mixed-valence transition metal sites according to the electron self-exchange or electron hopping mechanism. This model is operative during partial electroreduction, i.e., injection of up to four electrons to a Keggin-type heteropoly structure of molybdenum and tungsten. Further reduction of heteropolytungstate or molybdate is irreversible and leads to the formation of so-called heteropolybrown species in which such distinct ionic sites as W^{VI} and W^{IV} or Mo^{VI} and Mo^{IV} can coexist (Bard et al. 2008).

The heteropolyanions undergo several rapid one- and two-electron reversible reductions to produce the so-called “heteropoly blue” and further irreversible multielectron reductions with concomitant decomposition. The electrons are accepted by the addenda ions of the heteropolyanions. If the addenda ions are all identical, the electrons are delocalized on the addenda ion oxide framework at room temperature by rapid electron hopping (intramolecular electron transfer). The reduction increases the negative charge density at the heteropolyanions and thus their basicity.

As a consequence, the reduction can be accompanied by protonation depending on the pK_a of the produced oxometalates (Sadakane and Steckhan 1998).

Keggin-type heteropolyanions can accept a limited number of electrons without decomposition, and in some cases the reduced compounds have been isolated.

With increasing pH, the third reversible two-electron wave moves to a more negative potential and splits into two reversible one-electron reduction waves at pH 4:

For phosphopolyoxomolybdate, it is difficult to obtain well-defined redox waves in cyclic voltammetry in aqueous electrolytes due to the easy hydrolysis of $PMo_{12}O_{40}^{3-}$. However, it is stabilized by addition of comparatively large amounts of organic solvents. The reduction potentials depend on pH as a result of protonation (Sadakane and Steckhan 1998; Gómez-Romero and Casañ-Pastor 1996).

Dawson-type heteropolyanions undergo several reversible one-electron reductions in organic and aqueous solvents if no protonation accompanies the reductions.

The stability of tungstophosphoric acid in aqueous solutions is considerable dependent on pH with regard to the dominant species present in the solution (Holclajtner-Antunović et al. 2008). Many factors influence the equilibrium, primarily pH and HPA concentration, while the performance of different analytical techniques used for speciation should be taken in account as well. Tungstophosphoric acid decomposes first to components of the Dawson series, while the total decomposition of the Keggin anion to phosphate and tungstate occurs at $\text{pH} > 7.5$.

It should be noted that, besides the ability to perform multielectron redox transformations, HPAs also have a very strong Brønsted acidity approaching superacid region. Their acid-base and redox properties can be varied over a wide range by changing the chemical composition (Damjanović et al. 2005). HPAs catalyze a wide variety of reactions in homogeneous liquid phase. Being stronger acids, HPAs will have significantly higher catalytic activity than mineral acids. HPA catalysis lacks side reactions such as sulfonation, chlorination, nitration, etc., which occur with mineral acids (Kozhevnikov 1998).

Multifunctional Responsive Membranes

► Magnetically Responsive Membranes

Multilayered Thin Film Composite Membranes

Suzana Pereira Nunes

Division of Biological and Environmental Sciences and Engineering, Nanostructured Polymeric Membranes Lab, King Abdullah University of Science and Technology (KAUST), Thuwal, Saudi Arabia

A thin film composite (TFC) membrane is a bilayer of multilayer membrane constituted by

Multilayered Thin Film Composite Membranes,

Fig. 1 Interfacial polymerization in the formation of thin film composite membranes

an asymmetric porous structure and a thin and dense-selective film. The asymmetric structure gives mechanical stability to the membrane, without restricting flux. It is normally obtained by phase inversion and frequently based on polysulfone. In the most known TFC membranes, the thin layer is based on polyamide and is prepared by interfacial polymerization (Nunes and Peinemann 2006). Having a typical thickness lower than a micrometer, the dense layer gives the needed selectivity for salt (reverse osmosis) or other small solutes, without adding a high barrier for water transport. Interfacial polymerization as a simple and effective method for TFC membranes started to be explored by Cadotte et al. (1980) in the 1960s. Initially polyethylenimine and diisocyanate were used as monomers, resulting in what was known as NS-100 membrane. The most used system for thin film preparation is currently a combination of m-phenylenediamine (MPD) and trimesoyl chloride (TMC), as shown in Fig. 1. The porous asymmetric support is filled with an aqueous solution of MPD and immersed in an organic solution containing TMC (e.g., in hexane). By choosing immiscible solvents, the reactants will only contact each other at the interface. The reaction takes place immediately to form a defect-free polymeric film. Once the film is formed, the monomers are no longer in contact anymore, limiting the thickness. The system in Fig. 1 led to the development of reverse osmosis membranes such as FT-30,

commercialized by Dow, which has dominated great part of the desalination market with salt rejection higher than 99.2 % and fluxes of around $1 \text{ m}^3 \text{ m}^{-2} \text{ day}^{-1}$.

Comprehensive reviews on thin film composite membranes for reverse osmosis and nanofiltration were published by Petersen (1993) and, more recently, by Lee et al. (2011).

Despite of the success of the polyamide membranes shown in Fig. 1, a drawback is still the chlorine resistance, which was also poor for the NS-100. Other chemical compositions have been proposed over the years to improve resistance, such as polypiperazine-amide-based films. However, the overall combination of high flux and salt rejection is the most important target. The development of TFC membranes had a strong contribution to the widespread implementation of desalination plants from seawater.

TFC membranes are now applied also for emergent processes such as forward osmosis and pressure retarded osmosis. The requirements for these applications are different, which operate at much lower pressure than reverse osmosis (RO). High flux is even more important. While the resistance to compaction is not as important as for RO, an opener support is desired to avoid accumulation of draw solutes in the membrane and concentration polarization effects.

A typical ridge-and-valley structure is observed on TFC membranes, as seen in Fig. 2.

Multilayered Thin Film Composite Membranes, Fig. 2 Scanning electron microscopy image of a polyamide TFC membrane

The morphology of the thin layer is affected by the porosity of the substrate. Larger pores can promote convection at the interface during the polymerization and a rougher structure. Changes in the monomer concentrations and addition of solvents of intermediate miscibility affect the morphology and thickness, as well as the integration of hydrophilic intermediate layers (Livazocic et al. 2015). More recently TFC has been applied to filtration in organic solvents (Karan et al. 2015) reaching permeances of more than $112 \text{ l m}^{-2} \text{ h}^{-1} \text{ bar}^{-1}$.

Apart from the thin film composite membranes prepared by interfacial polymerization, other methods can be used to form a selective layer leading to composite membranes:

- (a) Dip coating of a diluted polymer solution on a porous support, followed by solvent evaporation
- (b) Film deposit by plasma
- (c) Separated casting, delamination, and deposit on a support
- (d) Dip coating of a monomer solution, followed by reaction (e.g., by UV radiation or heat)

Multivariate Analyses

Rocco Caliendo

Institute of Crystallography, CNR, Bari, Italy

Multivariate analysis techniques allow more than two variables to be analyzed at once. Two general types of techniques exist: (i) analysis of interdependence, where no variables are thought of as dependent. These methods look at the relationships among variables and are unsupervised. (ii) Another is analysis of dependence, where one or more variables are dependent variables, to be explained or predicted by others. These methods are supervised and typically are constituted by multiple regression.

Data, for example, acquired spectra, are arranged into a table (matrix) in such a way that each row represents one sample and each column

Multivariate Analyses, Fig. 1 Score plot of the first two principal components and related X-ray diffraction profiles of glycine polymorphs produced in membrane crystallization experiments. 90 % confidence level ellipsoids are drawn

one measured variable (Kvalheim 1988). When the number of variables increases, the challenge is to find low-dimensional, information-rich projections of both variable and sample space since the full spaces cannot be displayed and comprehended in a simple manner. This task can be achieved by projecting onto latent variables (Rajalahti and Kvalheim 2011). The oldest and most common latent variable projection method is ► **Principal Component Analysis** (PCA) (Jackson 1991; Wold et al. 1987). The data matrix $\mathbf{X}$ is decomposed into a number of principal components (PCs) that maximize explained variance in the data on each successive component under the constraint of being orthogonal to the previous PCs. An example is given in Fig. 1, where clear classification of glycine polymorphs obtained by membrane crystallization processes is achieved by applying PCA to X-ray diffraction data (Di Profio et al. 2013). Drawbacks of PCA are that the criterion for the latent variables does not always guarantee the perfect separation among group of data and that it cannot be applied for quantitative analysis.

Supervised regression methods are instead used to build a model to interpret data and to produce predictions by using such model. Regression is a mathematical method for determining the

best equation that reproduces a data set, and it is supervised because input data are divided into two subgroups: a training or calibration set, from which data are used to estimate model parameters, and a test or prediction set, from which data are used to get an independent assessment of model efficacy and to produce predictions. Regression models should avoid data over-fitting (see, e.g., Fig. 2), which occurs when a surplus of parameters causes an over-interpretation of the calibration set, with a consequent poor efficacy in predicting outputs for the prediction set. The most common regression method is Least Square Fitting, where the best fit of a function (model) to experimental data is found. The fitting is based on the minimization of the sum of the squared residues between model and experimental data. Another widespread method is Partial Least Squares, where the dependent variable Y is filled by known responses for the calibration set and with predicted ones for the prediction set. The regression model is built by finding the maximum covariance between Y and the independent variable X .

Performances of multivariate techniques can be enhanced by data pre-processing, which are specific for the kind of data, and produce rescaled data from original ones. Common pre-processing

Multivariate Analyses,

Fig. 2 Example of over-fitting in regression. True (blue line) and estimated (red line) trends are superimposed to experimental data (empty circles)

techniques are mean centering, standard normal variate, normalization, and background subtraction.

Vibrational spectroscopy, such as infrared, near infrared, and Raman, X-ray diffraction, and imaging techniques are characterization methods that have been applied in membrane technology applications to monitor physical and chemical phenomena occurring during the processes. These techniques produce data with high dimensionality, since each sample is described with hundreds or even thousands of variables.

Multivariate methods can play a critical role in process understanding, multivariate statistical process control (MacGregor and Kourti 1995), fault detection and diagnosis, and process control and process scale-up.

Multivariate Image Analysis (MIA)

René Ruby-Figueroa

Institute on Membrane Technology, National Research Council of Italy, ITM–CNR, Rende, Italy

MIA was originally proposed in the late 1980s (Geladi et al. 1989; Esbensen and Geladi 1989; Geladi and Esbensen 1989). It consists basically in the application of multivariate chemometric methods to enhance the quality of images that has usually been obtained using spectra recorded over a range of wavelengths. A digitized image is usually composed of pixels, which are small “dots” on the screen. Each pixel contains some information presented normally as a color of a given intensity on the photographic or microscopic image. The image can be unfolded and so treated as a long data matrix, with one dimension corresponding to all the pixels in the image and the other to the wavelength ranges or spectra. Generally, this matrix is then transposed so that the pixels represent rows and the columns spectral

frequencies. This provides an unsupervised classification of the image pixels based on their spectral signature which can be observed in the score space $\mathbf{T}$ of the PCA model. The information contained in the image is then explored and interpreted by iteratively segmenting regions of interest in the image feature space $\mathbf{T}$ (i.e., PCA score space) and overlaying the identified pixels on the original image scene. This is often referred to as the masking procedure by which spectral features are extracted from the image (Brereton 2007).

MIA involves a series of steps from image acquisition to obtain the desired information (i.e., prediction, monitoring, and control schemes). After acquiring digital images (e.g., infrared-IR, Raman microscopy, satellite images, NMR, medical images, X-ray, or near-infrared images), these should be preprocessed or filtered to enhance the image quality as well as to remove irrelevant sources of variation. Subsequently, a vector of relevant features is extracted from each image. This step is definitely the most critical part of the framework, due to sensitivity and robustness of the final machine vision system which strongly depend upon the responsiveness of the features to the desired information to be obtained from the analysis. Therefore, it is required to determine the type of features to investigate, i.e., spectral features, textural features, or a combination of both. The key issue of this step is to determine if the desired information is proportional to the number of pixels, colors, or spectral signatures. The traditional approach for extracting features from multivariate images consists of iteratively segmenting the score density histograms (i.e., masking in the feature space $\mathbf{T}$) and overlaying the selected pixels in the original image space where the segmentation quality is assessed. In this approach, the masks in the feature space $\mathbf{T}$ are adjusted by trial and error until satisfactory segmentation of the image is achieved. Since no $\mathbf{Y}$ data is used in the masking procedure, a priori knowledge of the objects to be captured in the image space is required (Duchesne et al. 2012).

Posteriorly, image features are analyzed by using empirical models such as principal

component analysis (PCA), partial least square (PLS), and partial least square discriminant analysis (PLS-DA). PCA has been used for unsupervised image classification. For further classification analysis, incorporating class data, PLS-DA can be used. On the other hand, when the objective is to build inferential models for process response variables or product properties $\mathbf{Y}$ (i.e., membrane characteristics), MIA based on PLS provides predictions, after previous model calibration and validation.

Several applications of MIA have been reported in various fields such as the analysis of pharmaceutical tablets to determine the distribution of excipients and active drugs, associated at properties like solubility (Brereton 2007). Other applications are focused on multivariate images obtained from fields of remote sensing (satellite imagery) (Esbensen and Geladi 1989), analytical chemistry (e.g., NMR) (Geladi and Grahn 1996), and medical imaging (e.g., MRI) (Geladi and Grahn 1996). Application of MIA in the process industries is more recent. Bharati and MacGregor (1998) advocated the use of MIA for online process monitoring by applying the method to a time series of images. Since process images are generally acquired in a sequence, computing the number of pixels having a specific spectral signature (i.e., falling under a mask) in each image of the sequence could be useful to monitor the frequencies of occurrence of certain abnormal process events or product defects (Bharati and MacGregor 1998).

The application of MIA approach to membrane characterization is an interesting challenge not yet covered. Membrane images can be used for predicting various response variables ($\mathbf{Y}$) such as pore size, pore size distribution, thickness, water permeability, selectivity, etc.

Nanoclays

Hongyang Ma, Benjamin S. Hsiao and Benjamin Chu
Department of Chemistry, Stony Brook University, Stony Brook, NY, USA

Nanoclays are mainly formed from volcanic ash or rocks with unique layered structure. Typically, silica and alumina are the dominant constituents of clays, with two types of sheeting structure as silica tetrahedral and alumina octahedral sheets. Each clay layer includes two tetrahedral sheets and one octahedral sheet. The silica tetrahedral sheet consists of SiO_4 groups linked together to form a hexagonal network, while the alumina sheet consists of two planes of close-packed oxygens or hydroxyls between which octahedrally coordinated aluminum atoms are imbedded. The two tetrahedral sheets sandwich the octahedral, sharing their apex oxygens with the latter. One of the major family members in nanoclays is natural montmorillonite, generically referred to as nanoclay, which is mainly used to create nanocomposite with polymer materials such as nylon 6 (Picard et al. 2007). We assume the

individual nanoclay stack possesses cylindrical symmetry about its stack axis, and the axes of all the nanoclay stacks are preferentially oriented with respect to the film normal. In other words, the film possesses fiber symmetry as illustrated in Fig. 1a. For the edge-on scattering geometry, it will refer to the vertical direction as the “meridional” direction and the horizontal direction as the “equatorial” direction. For a system with moderate orientation of nanoclay stacks, the meridional scattering in the edge-on SAXS is arc-like, which can be factored into a radial and an angular component. Figure 1b reveals that there is no large aggregation of nanoclay stacks in the polymer matrices, and the homogeneous dispersion of nanoclays in the polymer matrix is achieved. The polymer chains penetrate in between the layers of the nanoclays and break them into individual sheet (Nawani et al. 2010).

The polymer/nanoclay nanocomposite membranes are mainly applied in gas separation, pervaporation, and fuel cell system, where the nanoclay is used to improve the proton conductivity, gas diffusion, methanol permeability, as well as mechanical properties of the membranes (Alonso et al. 2009; Marras et al. 2008; Anilkumar et al. 2008; Frounchi et al. 2006).

Nanoclays,

Fig. 1 Directional 2-D SAXS images simulated from disk-like nanoclays with cylindrical symmetry and preferred orientation (**a**) and a typical TEM image of polymer/ montmorillonite nanocomposite (**b**) (Nawani et al. 2010)

Nanocomposite Membranes

Fabio Bazzarelli and Lidietta Giorno
Institute on Membrane Technology, National Research Council of Italy, ITM–CNR, Rende, Italy

Synonyms

Mixed matrix membranes (MMMs)

Nanocomposite membranes or mixed matrix membranes (MMMs) are heterogeneous membranes having inorganic particles dispersed into polymeric matrices, with the aim of improving the performance of membranes by synergistic combinations of the properties of both components. The nanocomposite materials possess enhanced properties compared with the single organic or inorganic material. Such improvement is either with respect to separation performance (higher selectivity and permeability) or to physicochemical properties (hydrophilicity, porosity, charge density, and mechanical, optical, electrical, and thermal properties). In addition, the introduction of nanoparticles into organic polymers can improve the resistance to chemical reagents and antifouling properties in the water treatment processes.

Nanocomposite membranes appear as an interesting approach for overcoming the problem of the trade-off relationship between selectivity and permeability of the pure polymeric membranes (Robeson 2008). The properties of polymer composites depend on the nanoparticles that are incorporated, including their size, shape, concentration, and interactions with the polymer matrix. Numerous polymers, both in glassy and rubbery states, have been studied as continuous matrices in MMMs. Some glassy polymers were investigated including perfluorinated materials, polyimides, polysulfone, polyetheretherketone, and polymer of intrinsic microporosity (PIM-1). Rubbery polymers are also attracted as continuous matrices such as silicone, polyethylene, and polybutadiene. Often natural polymers (polysaccharides, collagen, and chitosan) are

also employed as the matrix. Nanoparticles of various natures were embedded in the polymer matrix. They have been widely used in optical, electrical, and magnetic fields. Nanoparticles consist of conventional fillers (zeolites, carbon molecular sieves (CMSs), silicas, and metal oxides) and alternative fillers (carbon nanotubes (CNTs), metal organic frameworks (MOFs), graphenes, and layered silicates) (Rezazazemi et al. 2014). The successful implementation of nanocomposite membrane depends on the dispersion and distribution of fillers in the continuous phase as well as for the interface compatibility between the particles and the polymer. The homogeneous dispersion of nanoparticle in composites is a challenge because of the immiscibility of polymer and nanoparticles due to a missing interaction. Therefore, it is necessary to modify the particles to overcome their tendency to aggregate and improve their dispersion in polymer matrices. The main defects at the polymer-particle interface, including interfacial voids or sieves-in-a-cage, rigidified polymer layer around the particles and finally the particle pore blockage. Surface modification of inorganic particles is a popular technique because it produces excellent integration and an improved interface between inorganic filler and the polymer matrix. There are two main approaches for modification of the surface of the nanoparticles: modification of the surface of the inorganic particles by chemical treatment and grafting of functional polymeric molecules to the hydroxyl groups existing on the particles (Hong and Chen 2015). Basically there are three general ways to prepare nanocomposite membranes, including: sol-gel process, *in situ*/interfacial polymerization and phase inversion method (Souza and Quadri 2013).

The *sol-gel* technique is the method most applied for the preparation of polymer-inorganic nanocomposite membranes with highly homogeneous and controlled morphology. In this method, organic monomers, oligomers, or polymers and inorganic nanoparticle precursors are mixed together in the solution. The inorganic precursors then hydrolyze and condense into well-dispersed nanoparticles in the polymer matrix.

Nanocomposite Membranes, Table 1 Several nanocomposite membranes and their applications

Polymer matrix/fillers	Application	Aim
Poly(butadiene)/MgO	Gas separation	Increasing CO ₂ permeability
Polyamide/CNTs	Reverse osmosis	Antifouling and antioxidant properties
		Improving flux
Poly(lactic acid)/graphene oxide	Packaging	Enhancement gas barrier performance
Nafion/CNTs	Fuel cell	Increasing electronic conductivity
Chitosan-gelatin/ZnO	Biomedical	Antibacterial and improving mechanical properties
Poly(vinyl alcohol)/zeolitic imidazolate frameworks (ZIF-8)	Pervaporation	Improving flux

In *in situ*/interfacial polymerization, the nanoparticles are well mixed with organic monomers, and then the monomers are polymerized. There are often some functional groups such as hydroxyl or carboxyl on the surface of the inorganic particles, which can generate initiating radicals, cations or anions under high-energy radiation, plasma, or other circumstances to initiate the polymerization of the monomers on their surface.

In the *phase inversion method*, the preparation of nanocomposite membranes can be grouped by the following general procedure:

- Separate preparation of a polymer solution and a suspension of inorganic material.
- Mixing of both resulting in a mixed matrix solution.
- Casting solution is cast as film (or spinning) followed by phase inversion process. It can be induced by evaporation of solvent, immersion precipitation using nonsolvent, or by thermal precipitation.

The development of nanocomposite membranes finds applications in different fields such as gas separation, pervaporation, fuel cell, packaging, and water and wastewater treatment. In addition, nanocomposite membranes are of huge interest to biomedical technologies such as controlled drug delivery, tissue engineering, dental applications, and bone replacement/repair. In Table 1 are reported some types of nanocomposite membrane and their applications.

Nanofiber

Hongyang Ma, Benjamin S. Hsiao and Benjamin Chu
Department of Chemistry, Stony Brook University, Stony Brook, NY, USA

Nanofibers are fibers with a nanoscale fiber diameter. They can be fabricated from a variety of natural or synthetic, inorganic, organic, or polymeric materials by using a range of technologies, with the most common example being electrospinning, which has been developed rapidly in recent years to fabricate mainly nanofibers from polymeric materials. In the early 1900s, Cooley and Morton invented electrospinning, based on Gray's observation of water behavior under the influence of electrostatics (Teo and Ramakrishna 2006). During the electrospinning process, a

polymer solution is charged and is flowed out of a spinneret, and a droplet is formed under an external electrostatic field. By increasing the applied voltage to be strong enough to overcome the surface tension of the polymer solution, a fine jet is ejected from the tip of the droplet, which now has a cone-shaped form, known as the Taylor cone. When the jet stream travels from the spinneret to the collector, the solvent is being evaporated, and a nonwoven fibrous scaffold is formed on the collector. The fiber diameter and the morphology of the nonwoven mat are affected by (1) both processes: how the jet is formed and what occurs when the jet stream travels from the spinneret to the collector; (2) the material parameters, such as solution properties (concentration, viscosity, and conductivity as well as nature of the polymer and that of the solvent used); (3) and processing parameters, such as applied voltage, solution flow rate, and distance between the spinneret tip and the collector, as well as temperature, humidity, etc. More and more researchers in the fields of nanoscience and nanotechnology have gradually realized the important potentials of this process, resulting in a flourishing of activities. One main attractive feature of electrospinning is the ability to fabricate nanoscale polymeric fibers from (sub)micron diameters down to nanometer diameters with potential advantages, such as large surface area per unit mass. Electrospun fibrous scaffolds can offer a broad range of applications, including (1) tissue engineering, (2) drug delivery, (3) filtration and gas storage, and (4) sensors and electrodes for use in electronics (Huang et al. 2003).

As an applications example of nanofibrous membranes, the electrospun nanofibrous membrane can be used to remove bacteria, viruses, dyes, and toxins through size exclusion and adsorption from contaminated water. The membranes possess higher permeation flux and lower pressure drop performance than conventional microfiltration membranes. Moreover, the high surface-to-volume ratio and the ability to functionalize the surface of nanofibers permit those membranes to remove toxic metal ions with a capacity comparable to those of typical absorbents (Ma et al. 2013) (Fig. 1).

Nanofibrous Microfiltration Membranes

Hongyang Ma, Benjamin S. Hsiao and Benjamin Chu
Department of Chemistry, Stony Brook University, Stony Brook, NY, USA

Nanofibrous microfiltration membranes are fibrous membranes with nanofibers acting as the barrier layer in a microfiltration process. Typically, the membrane has a two-tier structure, with a nonwoven fibrous mat as the substrate support layer, partially also for mechanical strength, and an electrospun nanofibrous scaffold as the top barrier layer, which can selectively

retain targets, either by size exclusion or surface adsorption from contaminated water resources.

A highly permeable nanofibrous microfiltration membrane has been designed and fabricated by using nonwoven polyethylene terephthalate (PET) mat as the substrate and an electrospun polyacrylonitrile (PAN) nanofibrous scaffold being deposited onto the substrate and with an option to have immobilized cellulose nanofibers deposited on the *surface* of PAN nanofibers by impregnation (Ma et al. 2011). The cellulose nanofibers are collapsed onto the surface of PAN nanofibers, forming a fibrous network with high degrees of adsorption sites (Fig. 1). The introduction of cellulose nanofibers tremendously increases the effective surface-to-volume ratio of the electrospun nanofibrous membrane. The surface of electrospun nanofibers can now have a negatively charged property, due to the carboxylate groups on the surface of cellulose nanofibers. Yet, the high porosity characteristics of the electrospun scaffold remain, as the fiber diameter of the electrospun membrane increases only slightly by adherence of the cellulose nanofibers onto those electrospun membranes. The integrated hierarchical structure with fiber diameters, ranging from microns to nanometers, now produces a membrane with high filtration efficiency including both high throughput and retention of specifically targeted species by a

Nanofibrous Microfiltration Membranes, Fig. 1 Nanofibrous microfiltration membrane impregnated with cellulose nanofibers (Sato et al. 2011)

combination of size exclusion and adsorption. The pore size of the membrane can be correlated with the fiber diameter forming the (electrospun) nanofibrous membrane (Ma et al. 2012), whereas the infused cellulose nanofibers offer the adsorption capability. Therefore, cellulose nanofibers can be used to bring two different filtration mechanisms, e.g., size exclusion and adsorption, in the filtration performance of nanofibrous membranes. The nanofibrous microfiltration membrane exhibits 0.2 μm in mean pore size, which could be employed to take out waterborne bacteria, such as *E. coli*, from contaminated drinking water with full retention, as well as positively charged viruses, dyes, and heavy metal ions, simultaneously.

Nanofiltration

Patrick Fievet

Institut UTINAM, University of Franche-Comté, Besançon, France

Nanofiltration (NF) belongs to the class of pressure-driven membrane processes for liquid-phase separations, which also includes microfiltration (MF), ultrafiltration (UF), and reverse osmosis (RO). The four processes make

Nanofiltration, Table 1 Positioning of NF within the pressure-driven membrane processes and its characteristics

Membrane processes	RO	NF	UF	MF
MWCO ^a		200–1000 Da	3–300 kDa	
Pore diameter	<0.5 nm	0.5–2 nm	2–100 nm	0.1–10 μm
Rejection of	Ions	Multivalent ions and molecules	Macromolecules and colloids	Microorganisms, particles, and colloids
Permeation of	Solvents	Solvents, monovalent ions and small molecules	Solvents, mono- and multivalent ions, and small molecules	Solvents and dissolved species
Pressure range (bar)	30–100	5–40	2–10	0.1–2
Osmotic pressure	High	Intermediate	Low	Negligible
Permeate volume flux ($\text{L h}^{-1} \text{m}^{-2}$)	10–70	40–100	50–500	100–1500

^aMWCO designates the molar mass of the smallest component that will be retained with an efficiency of at least 90 %. 1 Da = 1 g mol⁻¹

use of a hydrostatic pressure gradient to generate mass transfer and selective transport of chemical species through synthetic membranes and also to overcome the feed solution's osmotic pressure. They are distinguished by the size of the pores or species to be separated, the applied pressures, the permeate fluxes, etc. (Table 1). NF lies between UF and RO, and its applications thus combine the lower pressures and higher permeate volume fluxes of UF with the high retention of RO.

With pore sizes of the order of the nanometer, NF membranes can therefore retain species with very low molecular weight such as sugars, dyes, organic micropollutants, etc. They are also able to retain ions and exhibit a high selectivity between mono- and multivalent ions. This results from the combination of pore diameters of a few nanometers with electrically charged materials. Indeed, most NF membranes possess a fixed charge that results from dissociation of surface groups (such as carboxylic or sulfonic acids) when they are in contact with polar solvent and/or by adsorption of charged species. Since NF membranes have pore sizes of the same order of magnitude as the distances of action of electrostatic forces, ion exclusion mechanisms are affected not only by steric effects, which are due to the size differences between pores and solutes, but also by

electrostatic interactions involving the Donnan and dielectric effects.

Today, NF is mainly applied in drinking water purification process steps, such as decoloring, micropollutant removal, and water softening. Other applications of NF are separation of dye from textile effluents (Chakraborty et al. 2004), wastewater recycling in laundries, rinse water recycling in plating industry (Frenzel et al. 2006), removal of pesticides and herbicides from groundwater (Kiso et al. 2000), concentration/purification of pharmaceutical broths (Christy and Vermant 2002), concentration of antibiotics (Zhang et al. 2003), and concentration/desalination of lactoserums (Guizard 2000).

Most NF membranes are thin-film composite membranes of organic (polymeric) or inorganic (metal oxides) nature. They are commonly made of three distinct layers prepared from different materials, each having a particular role: (i) a macroporous support layer with a thickness of approximately 100–200 μm for organic membranes and 1–2 mm for inorganic ones, providing mechanical strength while allowing high liquid fluxes; (ii) an active layer whose thickness varies from ~ 10 to ~ 300 nm for organic membranes and being a few microns for inorganic membranes, which is responsible for the separation; and (iii) an intermediate thin layer of high permeation

allowing the deposition of the active layer and preventing the penetration of the latter in the macroporous support during the filtration process. Beyond this common structure, NF membranes have specific physical and chemical features related to their organic or inorganic nature. There is a large diversity of NF polymeric membranes, but cellulose esters, aromatic polyamide, and polyethersulfone are mainly used. Depending on the materials thereof, organic membranes can be used in a pH range from 2 to 11 and at temperatures less than 90 °C. They are sensitive to oxidizing agents, solvents, and surfactants. In general, they possess a negative fixed charge that results from dissociation of surface groups. Inorganic NF membranes are (mixed) oxides, generally of aluminum, zirconium, or titanium. Due to their material properties, they have very good chemical ($1 < \text{pH} < 14$) and thermal stability (maximum working temperature: 350 °C for TiO_2 , 400 °C for ZrO_2 , and higher than 900 °C for $\text{Al}_2\text{O}_3\text{-}\alpha$). An important property of these membranes is the amphoteric character of their surface hydroxyl groups (positively or negatively charged surface sites depending on whether pH is less or larger than the isoelectric point of the material) which allows to control the sign and the charge of the membrane by pH control.

NF membranes are mounted into modules that allow for convenient assembly and operation in modular systems. Polymer membranes are mainly set in spiral wound and tubular modules coming from technologies already mastered in the manufacturing of pressure-resistant RO modules. Changes in spacer grids have been made by some spiral wound module manufacturers in order to increase the turbidity level allowed in the modules. In the case of ceramic membranes, the design of the modules is similar to the one for MF and UF membranes but improved sealing systems enable to reach higher working pressures.

As for RO or UF, typical NF process operating steps include assembly, water flush, integrity testing, buffer flush, processing, recovery flush, cleaning, sanitization, disassembly, and storage.

Manufacturers of NF membranes in 2013 include Danske Separation System AS (DSS AS), Dow/Filmtec, Hoechst (French company Hoechst

and Hoechst Aktiengesellschaft, Separation Products), Koch Membrane Systems Inc (Koch International), Lenntech, Nitto Denko Hydranautics, Novasep, Osmonics (Desal-Osmonics-Autotrol SA; Desalination Systems Inc), PCI Membrane Systems Ltd (PCI, Guerin SA), Permionics, Polymem SA, Stork Friesland B.V., Tami Industries SA, and Vladipore ZAO NTC.

Nanofiltration (Transport Phenomena)

Patrick Fievet

Institut UTINAM, University of Franche-Comté, Besançon, France

Nanofiltration membranes are characterized by effective pore diameters ranging from ~ 1 nm to a few nanometers, and most of them acquire an electric charge when brought into contact with a polar

medium. The combination of nanometric dimensions pores with electrically charged materials implies that the separation of solutes results from complex mechanisms that may include steric hindrance and Donnan, dielectric, and transport effects.

NF membranes are usually described as a bundle of capillaries with effective structural features (pore size and thickness-to-porosity ratio) and electrical properties such as their effective volume charge density (defined as the number of moles of fixed charges per unit of pore volume). The standard theory of NF is based on a macroscopic description of transport, which is actually a simplified version of the so-called space charge model originally developed by Osterle and co-workers (Morrison and Osterle 1965; Gross and Osterle 1968; Fair and Osterle 1971). Within very narrow pores such as those of NF membranes, the electrical double layers cannot fully develop and overlap strongly. As a result, both the local electric potential and ion concentrations are almost radially constant (provided the electric charge carried out by the pore walls is not too high (Szymczyk et al. 1999)). Neglecting these variations yields the so-called homogeneous approximation. This approximation considerably decreases computational effort and is currently used in most studies devoted to transport modeling through NF membranes (Tsuru et al. 1990; Bowen et al. 1997; Wang et al. 1997; Palmeri et al. 1999; Yaroshchuk 2001; Labbez et al. 2002; Bandini and Vezzani 2003; Lefebvre et al. 2004; Lefebvre and Palmeri 2005; Oatley et al. 2005; Szymczyk and Fievet 2005; Déon et al. 2007).

Within the scope of the homogeneous model, the solute separation process is described in three steps. The first one is the solute partitioning at the interface between the feed solution and the pore inlet. Next, the transport of solutes through the membrane pores is considered. Finally, the last step is the partitioning of solutes at the interface between the membrane and the permeate. During the last decade, several transport models have been developed which mainly differ from each other by the equation used to describe the partitioning of solutes at the membrane/solution interfaces. However, all are based on the extended

Nernst–Planck (ENP) equation (Schlögl 1964) to describe the solute transport through the membrane. This equation describes solute transport in terms of diffusion under the action of the solute concentration gradient, migration under the action of a spontaneously arising electric field (in the case of charged solutes only), and convection due to solvent flow. The electric potential gradient arising to fulfill the zero electric current condition at steady state plays a substantial role in the transport of charged solutes through pores because it acts differently on cations and anions. Indeed, the spontaneously arising electric field enhances the molar flux of coions in the permeate direction whereas it diminishes that of counterions so as to allow the transfer in stoichiometric proportions of both species into the permeate compartment.

The ENP equation is frequently modified by hydrodynamic coefficients so as to take into account the effect of the finite pore size on both diffusion and convection (Deen 1987). Assuming that no direct coupling between ionic fluxes occurs (i.e., mutual friction between solutes is neglected (Hoffer and Kedem 1967)), the modified ENP for solute i reads as follows:

$$j_i = -K_{i,d}D_{i,\infty}\frac{d\bar{c}_i}{dx} - \frac{z_i\bar{c}_iK_{i,d}D_{i,\infty}F}{RT}\frac{d\psi}{dx} + K_{i,c}\bar{c}_iV \quad (1)$$

where j_i is the molar flux of solute i through the pores, $D_{i,\infty}$ its diffusion coefficient in the external solution (value at infinite dilution), $\bar{c}_i$ its concentration inside the pores at the x position along the pore, z_i its charge number, ψ the local electric potential inside the pores, V the solvent velocity inside the pores, $K_{i,d}$ the hindrance factor for diffusion inside the pores, $K_{i,c}$ the factor accounting for the effect of pore walls on the solute convective flux, R the ideal gas constant, and T the absolute temperature.

The three terms on the right-hand side of Eq. 1 represent the diffusive, electromigrative, and convective components of the molar flux j_i , respectively.

Hydrodynamic coefficients $K_{i,c}$ and $K_{i,d}$ depend on the ratio of solute to pore radius ($\lambda_i = r_{i,s}/r_p$, where $r_{i,s}$ is the Stokes radius of the solute i and r_p the pore radius). They depend not only on λ_i but

Nanofiltration (Transport Phenomena),

Fig. 1 Concentration polarization phenomenon. c_i^{feed} , concentration of solute i in the feed solution; c_i^{perm} , concentration of solute i in the permeate; c_i^m , concentration of solute i at the membrane surface; J_V , permeate volume flux

also on the radial position within the pore. However, the effect of the finite pore size on both diffusion and convection can be quite accurately estimated using the values of $K_{i,c}$ and $K_{i,d}$ at the pore center only (Deen 1987). Several approximate analytical expressions derived using the centerline approximation are available in the literature.

The solute molar fluxes j_i are related to the permeate volume flux J_V (based on membrane area) as follows:

$$j_i = V c_i^{\text{perm}} = \frac{J_V c_i^{\text{perm}}}{A_k} \quad (2)$$

where c_i^{perm} is the bulk concentration of solute i in the permeate and A_k the membrane porosity.

It should be noted that, as with any membrane separation process, the separation of solutes is also influenced by transport through the polarization layer, which is caused by solute accumulation in the boundary layer adjacent to the membrane. The pressure-driven fluid flow through a selective membrane convectively transports solute toward the surface membrane. The partially or totally retained solutes accumulate at the membrane surface generating a concentration gradient, which induces a diffusive flux of solute from the membrane surface toward the feed bulk (Fig. 1). The solute builds up at the membrane surface until the equilibrium between diffusive and convective solute fluxes is attained. The concentration in the membrane boundary layer is critical for both fouling and retention. The importance of the

concentration polarization phenomenon increases with the permeation flux because more species are then brought near the membrane surface under the action of convective flow. Similarly, an increase in the concentration of the feed solution leads to a more important polarization. Concentration polarization is generally considered as a reversible process that can be controlled by velocity adjustment, pulsation, or electric field.

Nanofiltration for Reuse of Sharpless Catalytic Systems

Frederico Castelo Ferreira

Department of Bioengineering, Instituto Superior Técnico, Institute for Bioengineering and Biosciences, Universidade de Lisboa, Lisbon, Portugal

Nanofiltration for reuse of Sharpless catalytic systems combines reaction and separation in a

single vessel, allowing successive reaction and filtration steps, to recycle the catalytic system in successive batches with isolation of the chiral product on the permeated solution. The Sharpless catalysis is a robust strategy for production of chiral 1,2-diols from olefins at high yields and enantiomer excesses, using a catalytic system based on OsO_4 or $\text{K}_2\text{OsO}_2(\text{OH})_4$ salt and a chiral dimeric ligand (Bolm et al. 2000; Kolb et al. 1994). Chiral ligands used are based on a *cinchona* alkaloid (dihydroquinidine or dihydroquinine) with phthalazina, pyrimidine, or indoline groups. The reaction requires a co-oxidant, which can be organic or inorganic, such as *N*-methylmorpholine-*N*-oxide (NMO) or $\text{K}_3\text{Fe}(\text{CN})_6$, respectively. The reaction media is conventionally an aqueous/organic (50 v/v% solvent) mixture with *tert*-butanol, methyl *tert*-butyl ether, or acetone. The feasibility of Sharpless reaction was also attained for a range of seven different olefins on the absence of organic solvent, using an aqueous system that includes a surfactant, such as sodium dodecyl sulfate and sodium cholate, or an ionic liquid such as hexadecyltrimethylammonium bromide (Branco and Afonso 2002; Branco et al. 2008). Moreover, the use of aqueous/surfactant or ionic liquid systems avoids the continuous gradual slow addition, required to obtain high enantiomer excesses in the aqueous/organic system. Widespread industrial application of the Sharpless system has been restricted by the high cost of the catalyst and toxicity of the osmium species. Aqueous and **organic solvent nanofiltration** had been assayed to isolate chiral product and recycle the osmium salt and chiral ligand hydroquinidine 1,4-phthalazinediyl diether (molecular weights, MW, of 368 Da and 779 Da, respectively) (Branco et al. 2008; Ferreira et al. 2007) into successive reactions. NMO with a molecular weight of 135 Da was used as co-oxidant for both aqueous/organic and aqueous/surfactant systems. Starmem120, a polyimide membrane with nominal **molecular weight cut-off** (MWCO) of 200 Da, was used for the aqueous/organic system, composed of a water/acetone (25 v% acetone) mixture, with a lower water content than in the conventional Sharpless system, to improve solvent mixture flux through the

Nanofiltration for Reuse of Sharpless Catalytic Systems, Fig. 1 Reaction scheme for asymmetric dihydroxylation of olefins

membrane (Ferreira et al. 2007). On the other hand, a ► **polyamide membrane**, Desal DK, with a MWCO of about 250 Da, was used in the aqueous/surfactant system to retain both catalytic system and sodium cholate (Mw 460.6 g.mol⁻¹), the surfactant used (Branco et al. 2008). In both systems, each reaction-membrane filtration cycle included a first reaction step at atmospheric pressure, without permeation, and a second ► **nanofiltration** step in which a pressure of 10–20 bar was applied as driving force to promote solution permeation through the membrane. The next cycle started by making up the feed volume with addition of solvent/water or only water in the water/surfactant system. Different steady states, concerning product concentration in the vessel, can be reached according with concentration factors (i.e., the ratio of initial per final volume) used. Product concentration can be important in the final process yield due to reaction inhibition by the product. ► **Diafiltration** strategies with feeding of additional solvent/water (or water alone) can also be employed in the ► **nanofiltration** step to reach lower product concentrations in the vessel and recovery higher product amounts in the permeate. However, for higher diavolumes, when catalyst and surfactant have rejections lower than 100 %, losses of the catalytic system into the permeate can become significant. Moreover isolation of the more diluted product from permeate is more challenging. Overall, the application of nanofiltration for reuse of the osmium catalytic system as the potential to improve turn over numbers (TON), (i.e., total product obtained by catalyst used) with beneficial impact on Sharpless reaction economics and osmium contamination of the product (Figs. 1 and 2).

Nanofiltration in Textile Industry

Darren Oatley-Radcliffe
 College of Engineering, Swansea University,
 Swansea, UK

The wastewaters generated from the textile industry are among the most polluting of all the industrial sectors and have been considered as a

significant environmental problem for several decades (Avlonitis et al. 2008). Dyes by very nature are chemically robust, are often toxic, and are typically in the molecular weight range of a few hundred Daltons. Most developed nations recognize the impact and toxicity of dyes that are released into the environment and have legislation in place to prevent such discharges necessitating the cleanup of such waste streams. There is great variation in the chemical nature of textile discharge which can vary dramatically depending on the type of product produced and chemicals involved in the particular textile factory. Due to the very stable nature of dyes, traditional technologies such as adsorption and physiochemical methods, photocatalysis and oxidative methods, and microbiological and enzymatic decomposition are of relatively little use in the recovery or destruction of dyehouse effluent. However, nanofiltration membranes have the potential to offer an improved separation and several cost advantages over these more traditional techniques, and various works have reported the use of NF membranes for dye separations either for wastewater treatment (Nataraj et al. 2009; Mo et al. 2008) or process applications (Levenstein et al. 1996). In most cases, the dye wastewater also contains residual salt from the manufacturing process. The removal of dye should be high, but not necessarily complete, and the fate of the salt is of less importance. A review of NF processes in the textile industries has been compiled by Lau and Ismail (2009) and has indicated that most commercial membranes either achieve a maximum separation of the dye or high membrane flux. The desirable ideal membrane should exhibit both characteristics. The ideal separation when considering nanofiltration membranes should utilize both the steric and Donnan separation effect. For example, if one considers the separation of a waste containing a mixture of both Clayton Yellow (MW = 696 Da) and methyl orange (MW = 327 Da), then a neutral membrane with a MWCO of ~500 could potentially achieve this separation based on the steric effect. If one considers the separation of methyl orange (MW = 327 Da, negatively charged) from methylene blue (MW = 320 Da, positively charged),

then a negatively charged 600 MWCO membrane would potentially retain the methyl orange (Su et al. 2004) and a similar positively charged membrane would retain methylene blue (Cheng et al. 2012). In each of these cases, the resulting separation would most likely require a diafiltration process to achieve high purity dyes. In the case where the desired dye is in the permeate stream, then a reverse osmosis process to reconcentrate the dye may be required prior to any recycle. Similarly, where high salt levels exist in the dyehouse effluent, the same diafiltration process may be employed to separate the dye from the salt potentially facilitating the recycle of both materials. In all cases, water recovery and recycle from the effluent streams may be achieved using nanofiltration (or in some cases reverse osmosis) which can lead to a significant operational cost saving.

NF Membranes

General View

Nanofiltration membrane is a pressure-driven membrane, with a nominal molecular weight cut-off (molecular weight of solute that is 90 % rejected by the membrane) ranging from 200 to 1000 Da, pore size of around 0.2–2.0 nm, and operating pressures of 70–200 psi (5–15 bar) (Schäfer et al. 2002). Although a common belief indicates that NF and RO membranes do not possess distinct pores, as in ultrafiltration (UF) and microfiltration (MF) membranes, recent studies using atomic force microscopy suggest that pores of NF membranes can be viewed (Daraei et al. 2013).

In the early stages, nanofiltration membranes were named as ultralow-pressure reverse osmosis (RO), charged ultrafiltration, loose RO, tight UF, lower rejecting or open RO, and selective RO membranes (Schäfer et al. 2002).

The nanofiltration membrane was defined in 1987 by Simpson et al. (1987) in the first publication with the title of nanofiltration as: “These charged membranes possess properties lying between those of reverse osmosis and ultrafiltration membranes. Molecules with a molecular mass greater than 300–400 Da, e.g., glucose, are rejected and inorganic ions are selectively excluded according to their charge densities.”

Nanofiltration membrane is primarily used to separate low molecular weight organics and

multivalent salts from monovalent salts and water. They provide 50–90 % salt rejection at low-pressure operation. This reduces energy consumption and significantly lowers installation and operating costs.

Nanofiltration membranes provide specific advantages over conventional membranes. They exhibit higher flux at lower pressures versus reverse osmosis and improved rejection compared to ultrafiltration membranes.

Applications

In the early stages, nanofiltration membranes were employed in softening and natural organic matter removal for drinking water treatment. Nanofiltration membranes were grown rapidly due to unique capability of fractionating ionic and low molecular weight organic species. This type of membrane has been an important separation and purification technique in not only aqueous feeds such as water treatment and pharmaceutical purification but also emerging applications in organic solvent and ionic liquid-based separations. Currently, the application of nanofiltration membrane is growing in chemical, desalination, concentration and purification, paper, whey, semiconductor, textile, and leather industries and recycling of valuable homogenous catalysts.

The removal of heavy metals from wastewater, removal of pesticides from groundwater, recycling wastewater in laundries, water softening, and nitrate removal are the outstanding applications of nanofiltration membranes.

Nanofiltration in water treatment “bridges” a gap between ultrafiltration and reverse osmosis membranes. There are many applications where a 75 % rate of salt rejection is preferable to 99 %, especially when it is achieved using only half of the energy. Typically reverse osmosis membrane with less than 99 % sodium chloride removal is considered inferior. In the case of NF, there is a “place” for any membrane with NaCl rejection rate of 40 % or more.

Mechanisms

The major separation mechanisms of nanofiltration membrane involve a steric (size exclusion) effect and an electrostatic interaction (Donnan exclusion) between the membrane and an external solution. Charged membrane with a “loose” polymer structure enables separation of ions enhanced by Donnan exclusion. For nanofiltration membrane, both surface charge and sieving mechanisms affect the rejection of solutes, which are usually characterized by high retention of divalent ions, low rejection of monovalent ions, and high flux.

Size exclusion is a simplified retention model that is based on physical size of a contaminant. Usually the solutes larger than the pore size of the membranes are retained. This model is based on the sieving phenomenon. However, one should consider that the membranes neither have uniform pores nor the solutes have uniform size. The molecules are flexible in size and shape as a function of stress and solution chemistry. Moreover, trace contaminants may interact with other molecules or membrane polymer (via hydrogen bonding or hydrophobic interaction). This influences the retention.

Charge interaction is another model describing the transport of organic electrolyte across NF membrane. This electrostatic and steric-hindrance model combines space charge and steric hindrance. Based on this model, solute retention is a function of the ratio of charge density of the membrane to ionic concentration of the solvent and proportion of solute dimension in the solvent to pore size of the membrane. As a result, it is expected that retention of trace organics is influenced by solution chemistry such as pH and ionic strength.

Some trace organics may possess a negative or positive charge when the molecules dissociate at high or low pH. Negatively charged species often experience higher retention compared to uncharged molecules with the same size. This can be attributed to the electrostatic repulsion between the molecules and the negative

functional groups of the membrane. However, positively charged organics are poorly retained by the negative membranes.

The pH value of the feed solution may affect the membrane characteristics and the retention property. The most significant one is the membrane surface charge density which is often measured as zeta potential. In general, zeta potential of the membrane surface is changed from a positive to a negative value as the solution pH is increased. Subsequently, electrostatic interaction between an ionic compound and the membrane surface is varied according to the solution pH.

Adsorption of materials to the membrane surface or pores is another substantial aspect of contaminant removal using nanofiltration membranes. In fact, adsorption is recognized as the first step in the transport mechanism of water and in some cases solutes across the membrane in the well-known sorption-diffusion model. The adsorption is influenced by the charges of the molecules and membrane. This may enhance attraction or repulsion. Although adsorption contributes to initial high rejection, lower retention is often observed when the membrane has been gradually saturated.

Membrane Preparation and Modification

Most commercial nanofiltration membranes are fabricated from organic polymers. However, inorganic membranes composed of metal oxides are developing due to higher durability in numerous applications. The main goal in membrane preparation is to control membrane structure to properly affect the membrane performance.

The nanofiltration membranes may be manufactured using the conventional techniques including the well-known phase inversion and interfacial polymerization approaches. However, the preparation of nanofiltration membranes with improved properties by new materials or advanced modification methods for existing membranes is a valuable and practical technique.

A potential approach to develop new NF membranes is to modify UF and RO membranes via various procedures.

There are numerous modification methods that improve the performance of nanofiltration membrane. Generally, surface modification of membranes by functionalization methods (coating, self-assembly, chemical treatment, plasma treatment, graft polymerization, molecular imprinting, and enzyme immobilization) and nanofiller embedment are the practical ways to modify polymeric membranes in general and nanofiltration membrane in particular (Zhao et al. 2013).

Presently, most nanofiltration membranes are assembled in spiral-wound configuration using thin-film composite flat-sheet membranes.

Nanotechnology Membrane

Abaynesh Yihdego Gebreyohannes and Lidietta Giorno

Institute on Membrane Technology, National Research Council of Italy, ITM–CNR, Rende, Italy

Over the last decade, nanotechnology has rapidly evolved from an academic research to commercial reality. The concept of nanotechnology led to the development of innovative nanotechnology-

based membranes that surpass the state-of-the-art performance and enable new functionality such as high permselectivity, catalytic reactivity, and fouling resistance. Nanotechnology is used to enhance performance of traditional ceramic and polymeric membrane materials through various strategies (Pendergast and Hoek 2011). Nanotechnology membranes include:

- Zeolite and catalytic nanoparticle-coated ceramic membranes
- Hybrid inorganic-organic nanocomposites membranes
- Bio-inspired nanotechnology membranes
 - Bio-hybrid immobilized enzyme membranes
 - Bio-hybrid magnetic-responsive membranes
 - Aquaporin membranes
 - Vertically aligned nanotube membranes
 - Isoporous block copolymer membranes

Hybrid Inorganic-Organic Nanocomposite Membranes

Mixed matrix membranes present the synergistic advantage of both the low cost and ease of fabrication of organic polymeric membranes and mechanical strength and functional properties of inorganic materials (Dong et al. 2013). The concept was first introduced in the 1990s by Zimmerman et al., as a strategy to overcome the limitations of polymeric membranes for gas separation. The most commonly exploited inorganic fillers are alumina, carbon nanotubes, iron-palladium particles, silica, and titania, which are embedded within the polymeric matrix. The particle size covers broader ranges from 0.5 to 300 nm, while the general composition ranges from 0.01 to 40 wt.% (Pendergast and Hoek 2011). Generally, inclusion of the inorganic particle imparts change in the polymeric membrane surface property (hydrophilicity/hydrophobicity, roughness, increased or decreased water permeability and selectivity depending on the type, size, and weight fraction of the inorganic particle, improved thermal and mechanical stability, as well as enhanced antifouling property).

In addition to microparticles, nanoparticles have been added to polymeric membranes, e.g., the inclusions to the thin films of thin-film composite (TFC) reverse osmosis membrane have been of great interest to impart the properties of the nanomaterials. Embedding smaller nanoparticles increases permeability more by increasing the characteristic pore size. One of the main reasons attributing to the enhanced permeability of the TFC membranes with embedded nanoparticles is the presence of limited cross-linking than pure polyamide TFC counterparts. Overall, the addition of nanoparticles can be tailored to particular membrane applications with the selection of nanoparticle size, shape, and type. Furthermore, inclusion of the nanoparticles such as silver in the TFC could inhibit biofouling growth due to the antimicrobial property of nanosilver (Basri et al. 2010).

Nevertheless, improved permselectivity through inclusion of nanoparticle to the TFC may not be a general fact. It is theoretically predicted that the permeability of TFC, which have impermeable nanoparticles like titania, reduces, while those containing permeable nanoparticles like SOD-zeolite increases. A nanoparticle with higher water permeability relative to the polymer matrix can increase the permeability of the resulting nanocomposite membrane, while impermeable nanoparticles can only reduce the water permeability of a membrane because they reduce the area available for permeation through the polymer film. The only time impermeable particle can enhance permeability is when they cause defect in the thin-film layer which also compromises their solute rejection capacity (Pendergast and Hoek 2011).

For the impermeable particles, even with the presence of loss in permeability, inclusion of the nanofillers could be desirable to induce hydrophilic or antimicrobial properties that significantly reduce membrane fouling. In addition to performance, one also has to take the cost of the nanofillers into consideration for practical application. For instance, antimicrobial and zeolite nanoparticles are expensive, yet zeolite nanofillers can bring about a considerable flux improvement at extremely low loadings such that the cost increase may be minimal.

Other interesting features one can induce by inclusion of nanofillers into polymeric membranes are stimuli-responsive properties. One of the main strategies that follows the research on stimuli-responsive organic-inorganic (O/I) hybrid membranes is the incorporation of superparamagnetic nanoparticles (NPs^{SP}). It is an emerging field that holds numerous unexplored interesting avenues (Daraei et al. 2013; Sanchez et al. 2011). It leads to stimuli-responsive “smart” polymeric membrane with properties that can be modulated in a reversible manner. For example, recently magnetic-responsive micro-mixing nanofiltration membrane is developed. The membrane was prepared by grafting magnetic-responsive nanolayers consisting of hydrophilic poly(2-hydroxyethyl methacrylate) (polyHEMA) flexible polymer chains with NP^{SP} attached to the chain ends. The chain oscillates in an oscillating magnetic field, induced mixing at the membrane-fluid interface that maximized the disruption of concentration polarization layer (Himstedt et al. 2011).

NP^{SP} has also been used as inorganic nanofillers in a PVDF membrane to impart desired surface functionality (Huang et al. 2012). The hybrid membrane has controlled porosity, texture, and chemical composition that can provide real prospect to an efficient membrane filtration. The presence of the NP^{SP} also induces magnetic property in the membrane that can be controlled by an external magnetic field through remote on-off switches (Daraei et al. 2013; Thevenot et al. 2013). This responsive behavior, for example, is useful to manipulate the deposition of magnetic nanoparticle on the membrane surface to prevent direct membrane-foulant interaction (Gebreyohannes et al. 2015). In addition to inducing magnetic properties, inclusion of the NP^{SP} is reported to enhance the membranes’ hydrophilicity, mechanical strength, compaction resistance, improved permselectivity, and antifouling property (Daraei et al. 2013; Huang et al. 2012). Therefore, these membranes have broad function ranging from environmental remediation to smart product manufacturing. Particularly, the synergistic antifouling property and improved permselectivity give the membrane a big prospect to be utilized in water purification. NP^{SP}-coated

membranes, for example, have been used for effective removal of natural organic matter (Yao et al. 2009), arsenic (Sabbatini et al. 2010), and copper (Daraei et al. 2012) during water treatment.

Bioinspired Nanotechnology Membranes

Biomimetic nanostructured membranes are formed either through directly embedding biomolecule into synthetic materials or by using functional molecules to modify synthetic materials to impart specific biological property. These hybrid biomimetic membranes combine the accurate structure of a biological pore with the durability, robustness, and the possibility to control the pore size and shape of solid-state nanopore membrane (Shen et al. 2014).

Biohybrid Magnetic-Responsive Membranes

Superparamagnetic nanoparticles (NPs^{SP}) are most often superparamagnetic iron oxide with zero memory of their magnetic property in the absence of an external magnetic field (Yeon et al. 2009). Polymer coatings and the introduction of various surface functional groups facilitate the anchorage of biomolecules on the surface of these particles (Miguel-Sancho et al. 2012; Brullot et al. 2012; Xiao-Ming and Wainer 1993). The resulting bionanocomposites represent an important material with a versatile application in the biotechnology, fine chemicals, drug delivery, cell transplantation, or cell immobilization. These nano-sized particles exhibit biocompatibility, high surface-to-volume ratio which makes them a good candidate for enzyme immobilization to make biohybrids. The high surface-to-volume ratio assists with higher enzyme loading capacity and enhanced mass transfer efficiency. Hence this material with its excellent mechanical, optical, electrical, ionic, and catalytic properties is a good candidate to reversibly immobilize enzyme on the surface of a polymeric membrane to mimic hybrid protein-polymer biomimetic membranes.

Alternative to direct integration of the enzyme within the polymer matrix, stimulus-responsive

programmable layers on membrane can be formed through the attraction of NP^{SP} through reversible magnetic force. These biomimetic smart layers will enable development of adaptive enzyme membrane reactors. For instance, once an enzyme is immobilized on NP^{SP}, they can be easily dispersed in a reaction medium in the absence of an external magnetic field. However, by applying an external magnetic field, it is possible to relocate the bionanocomposites toward the surface of a membrane using an external magnetic field. The method is promising to resolve pertinent issues related to the direct integration of enzyme within the polymeric matrix. Overall, tuning reversible enzyme immobilization using NP^{SP} helps in:

1. Easy recovery, recycling, and removal of immobilized enzyme
2. Formation of dynamic layer between membrane and feed preventing membrane-pollutant interaction
3. Activation of the monolayer with biocatalyst to achieve biocatalysis at the membrane-solution interface
4. Easy regeneration of membrane whenever the membrane is oversaturated with substrate

This approach has recently been demonstrated to form an enzyme membrane reactor (Gebreyohannes et al. 2015). The method is novel for it has used NP^{SP} as a carrier to anchorage various enzymes as well as nanofiller to form magnetic-responsive hybrid membrane. When an external magnetic field has been applied to the system, the magnetic-responsive polymeric membrane gets magnetized. Subsequently, the NP^{SP} with the immobilized enzyme was dispersed in the upper stream. These particles were then attracted toward the surface of the membrane. The magnetic-responsive membrane acts as magnetic field actuators that eventually help with uniform dispersion of the NP^{SP} on the surface of the membrane. Hence it has potentially mimicked the micro-nanoarchitecture of the direct integration of enzyme into the membrane.

The method has shown an interesting performance when it was applied to treat a feed rich in polysaccharides. After depositing 1–2 g/m² of

pectinase activated NP^{SP} with an average diameter of 8 nm, 40 % to 100 % reduction in the pressure required to keep flux constant at 17 L/m² h was observed. Moreover, thanks to the easy recycling of enzyme, both membrane and immobilized enzyme were used over several cycles, adding a considerably extended lifetime to the membrane as well as the enzyme (Gebreyohannes et al. 2015).

Modulating reversible enzyme immobilization through combinatorial stimulus-responsive enzyme immobilization technique holds a great potential in bioseparations, antifouling surfaces, and creating self-cleaning membranes. Hence, the future innovations on the basis of stimulus-responsive enzyme immobilization holds a bigger prospect to “reengineer” membrane biocatalysis that will lead to the design of more complex membrane systems that are capable of mimicking the nature.

Aquaporin Membranes

Aquaporins are the protein channels that control water flux across biological membranes. Water movement in aquaporins is mediated by selective, rapid diffusion caused by osmotic gradients (Agre 2006; Meinild et al. 1998). According to Zhu et al. (nd), the two major factors that control water transport are:

- (a) Osmotic permeability: molecular movement due to concentration differences resulting in net mass transfer
- (b) Diffusion permeability: random movement of molecules with no net mass transfer

In the first case, the water molecules transport in a single file through a narrow aquaporin channel, while in the second case, permeation occurs due to the movement of two molecules between opposite pools. Hence, the ratio of the osmotic permeability to diffusion permeability is the number of effective steps a water molecule shall move in order to permeate through a channel. Since aquaporin channels have high water selectivity, a membrane with 75 % aquaporin coverage is predicted to have an order of magnitude higher water permeability compared to commercial seawater RO membranes (Kaufman et al. 2010).

There already are interesting research activities on the inclusion of aquaporins in polymeric membranes. For instance, the use of aquaporin-Z from *E. coli* bacterial cells used to form a protein-polymer membrane exhibited an order of magnitude higher water permeability as compared to a counterpure polymeric membrane. However, practical application of these proteins is highly limited by lack of large quantities of protein production. Nevertheless, with a continued research and effort, techniques to simplify the fabrication and production of mechanically sound membranes aquaporin-based biomimetic membranes are inevitable.

Vertically Aligned Carbon Nanotubes

Carbon nanotubes (CNTs) exhibit the fast mass transfer resemblance to aquaporin water channels in which water transport is two to five times higher than theoretically predicted by Hagen-Poiseuille equation (Holt et al. 2006). Molecular dynamic simulation studies attributed this outstanding flow rate to atomic smoothness and molecular ordering. In particular, water molecules permeate through the CNTs in a one-dimensional single file resulting in very small driving force use. Moreover, CNT-based membrane represents excellent mechanical properties that impart longer lifetime than conventional membrane materials.

The most commonly utilized mechanism used to produce uniformly aligned nanotube arrays is chemical vapor deposition (CVD). The CNTs are adapted by fixing surface functional groups to mimic aquaporin structure or by CVD and a simultaneous solid-state reaction (Holt et al. 2006). The pore densities of the CNTs made by fixing negative surface functional groups are as high as $0.25 \times 10^{12}/\text{cm}^2$ while representing three order of magnitude higher water flux relative to what is predicted theoretically. However, CNTs' alignment via CVD has a number of limitations such as its costliness, sensitivity, and difficulty for large-scale application. Alternative to CVD, magnetic alignment, self-assembly, and passing single-walled CNT suspensions through polymeric filters are approaches to form CNT-aligned membranes.

Although CNT mimicked biological aquaporin channels with a material producible in large

amount, no large-scale CNT-aligned membranes have been produced yet. However, one can resolve these challenges similar to the challenges faced by reverse osmosis membranes 50 years ago when performance improvements lead to the practical necessity of CNT-aligned membrane application.

Natural Gas Sweetening

A. Baudot
Physics and Analysis Division, IFP Energies
Nouvelles, Solaize, France

Introduction

Though raw natural gas is mainly composed of methane (generally from 75 % to 90 %), it also contains undesired components such as acid

gaseous impurities such as carbon dioxide or hydrogen sulfide that should be removed in order to prevent pipeline corrosion.

Permeation Membrane-Based CO₂ Removal

Gas permeation constitutes the latest carbon dioxide extraction technology applied to natural gas treatment. Membranes offer several strong advantages over conventional solvent columns: compacity (which makes membranes particularly well-suited for offshore operations (Cooley and Dethloff 1985)), low investment costs, low maintenance costs, and at least with single-stage configurations that do not operate compressors. The current level of commercial membranes CO₂/CH₄ selectivity is comprised between 12 and 25 in field conditions (Baker 2002; Roman et al. 2001; White et al. 1995; Baker and Lokhandwala 2008).

Several studies have been carried out since the adoption of membranes by natural gas operators, aiming at comparing membrane-based carbon dioxide removal operations with conventional absorption operations. Several trends can be issued from these studies, depending on the various considered gas treatment scenarios:

- Moderate natural gas flows (lower than 25,000–30,000 Nm³/h (Chapel and Mariz 1999; McKee et al. 1991)) containing high carbon dioxide concentrations: it appears that membranes are more profitable than absorption processes. In 1995, it was shown that commercial permeation membranes were more competitive than DEA/MDEA-based absorption when the carbon dioxide content was higher than 20 % (Meyer and Gamez 1995). Another study realized by Kellogg & Co. sets this limit at approximately 16 % for a gas price of 1.5 USD/MMBtu (McKee et al. 1991).
- High natural gas flows with low carbon dioxide concentrations: absorption processes prove to be more profitable than gas permeation modules.
- High natural gas flows combined with high carbon dioxide content: an association of

membranes and absorption seems to be the most profitable option (McKee et al. 1991). Membrane modules, located before the absorption column, carry out a bulk removal of carbon dioxide, while the absorption columns allow the final polishing of the natural gas.

Permeation Membrane-Based Hydrogen Sulfide Removal

Three main types of polymer membrane have been only tested at lab scale or pilot scale in order to remove hydrogen sulfide from natural gas.

Membranes Based on Rubbery Polymer Selective Layers

This type of polymer materials generally offer very high permeability values for low molecular weight components. The selectivity of this type of polymer is then essentially based on the affinity (i.e., the sorption coefficient) difference between several components to be separated. In the literature, three main polymer families can be identified:

- Apolar rubbery polymers, such as silicones (PDMS and PTMSP). As a general rule, the H₂S/CH₄ selectivity of these materials is rather modest, as methane diffuses more rapidly than hydrogen sulfide (Merkel et al. 2001).
- Apolar rubbery polymers impregnated with polar solvents: two patents have been issued by UOP in the mid-1980s about the use of PEG- or glycerol-impregnated silicone membranes. The addition of polar solvent, which displays a high affinity for hydrogen sulfide, leads to a very significant increase of the selectivity of these membrane materials toward hydrogen sulfide (Kulprathipanja and Sudhir 1985; Kulprathipanja 1985).
- Polar rubbery polymers: these types of polymer have mainly been studied by academic teams and display high values of H₂S/CH₄ selectivities associated with high H₂S permeabilities. To the authors' knowledge, though, those materials have not been studied on larger scale than at lab (Chatterjee et al. 1997; Orme and Stewart 2005).

Membranes with a Selective Layer Made of Block Polymers

This type of membrane materials has been principally studied by *MTR Inc.* which has developed commercial spiral-wound membranes with a selective layer made of various polyether block amides (commercialized under the trademark PEBAX[®] by *Arkema*). Tests under industrial conditions were conducted on production facilities operated by Shell and located in West Texas (Amo et al. 1998). It was shown that the PEBAX[®]-based membranes/sulfatreat process association was leading to significant operation costs (from 20 % to 40 %) over amine process alone for flow gases containing few percents of H₂S and lower than 140,000 Nm³/h while a PEBAX[®] membrane/amine coupling was more valuable than a stand-alone amine process for gas flows containing more than 5 % H₂S and higher than 23,000 Nm³/h.

Membranes with a Selective Layer Made of Glassy Polymers

Those stiff polymeric materials, used mainly for commercial carbon dioxide removal applications (polyimides, cellulose acetate, polysulfones), have their selectivity mainly based on molecular sieving effects. Despite their affinity for polar compounds (those membranes are also recommended by membrane manufacturers for gas dehydration applications), it appears that those membrane materials have rather low H₂S/CH₄ selectivities (Hao et al. 2008; Bhide et al. 1998). This can be mainly attributed to the fact that the kinetic diameters of hydrogen sulfide and methane are rather close, resulting in close values of their respective diffusion coefficients through glassy polymer-based selective layers.

Natural Organic Matter (NOM)

Tony Fane

School of Chemical Engineering, The University of New South Wales, Sydney, NSW, Australia
Singapore Membrane Technology Centre,
Nanyang Technological University, Singapore,
Singapore

Natural organic matter (NOM) is an organic material from environmental origin and produced by biodegradation of organic substances (plants, etc.).

NOM gives surface waters a brownish color and is a problem in drinking water supply, not because of its toxicity but because some of its components can react with chlorine used as disinfectant. The reaction by-products include trihalomethane, haloacetic acids, chlorophenols, etc. which are potentially carcinogenic. The NOM components are known as trihalomethane precursors (THMPs), and it is recognized that their removal prior to disinfection is important for public health. Membrane technology is frequently used for treatment to remove NOM from surface waters (see ► [Natural Organic Matter, Removal and Fouling of](#)).

Natural organic matter (NOM) has a broad spectrum of molecular weights and size distributions, functional groups, and substructures. The term NOM covers the particulate colloids (POM), “dissolved” colloids, and macromolecules or dissolved organic matter (DOM) and the humics. Since NOM is from environmental origin, its composition is highly variable both spatially and temporally. One of the major groups in NOM is humic substances (HS), which include a complex mixture of organic compounds such as humic acids (HA), fulvic acids (FA), and other hydrophilic compounds. Typically, humic substances have molecular weights from a few hundreds to approximately 100,000 Da. They contain both aromatic and aliphatic components with carboxylic and phenolic groups attached to the aromatic rings. As a result, humic substances can be negatively charged as well as having hydrophobic and hydrophilic components. The humic fraction also has neutral components. The charge character is important as it influences interactions with other pollutant species and the treatment process equipment (such as membrane surfaces).

The complexity of NOM makes characterization difficult. A review of methods can be found in Leenheer and Croue 2003. Recently NOM characterization has involved size exclusion chromatography, combined with UV and online DOC and organic nitrogen detection, in a system called “liquid chromatography-organic carbon detection-organic nitrogen detection” (LC-OCD-OND) (Huber 2014). This instrument provides a molecular weight distribution and also identifies components (in descending size) as biopolymers, humics,

building blocks, low MWt acids and humics, and neutrals. This measurement technique is now widely used in membrane applications to water and wastewater.

Natural Organic Matter, Removal and Fouling of

Tony Fane

School of Chemical Engineering, The University of New South Wales, Sydney, NSW, Australia
Singapore Membrane Technology Centre,
Nanyang Technological University, Singapore, Singapore

Natural organic matter (NOM) is present in surface waters and its removal prior to disinfection is important to avoid formation of potentially carcinogenic trihalomethanes (see “► [Natural Organic Matter \(NOM\)](#)”). With a size range from colloidal to a few hundred Daltons the NOM species are well suited to removal by membranes, including removal of trihalomethane precursors (THMPs). However, some of the components of NOM are potential membrane foulants, as discussed below.

Most typically, NOM removal involves microporous membranes (micro- or ultrafiltration), often in combination with a coagulant (ferri-salts, polyaluminium chloride, etc). The hybrid processes, combining membranes with chemical addition, give improved removals as seen in Table 1. The hybrid processes also provide

Natural Organic Matter, Removal and Fouling of,
Table 1 Typical removals of NOM by membranes

Process	TOC/DOC	THMP
	Removal (%)	Removal (%)
Microfiltration	10–40	15–20
MF + chemical	~80	~60
Ultrafiltration	~50	~40
UF+ chemical	~90	~80
Nanofiltration	90–99	90–99

better control of membrane fouling (see below). The disadvantage is the disposal of the waste sludge solids. Nanofiltration (NF), with pores in the 5–2 nm size range, is capable of high removals of NOM and is used extensively in Norway and Scotland, particularly in remote areas where chemical dosing would be troublesome. This advantage of NF may be offset by higher pressures and energy costs in some applications.

NOM fouling of membranes is complex with many influencing factors, including the variable nature of the raw water. It should be noted that no one single component of NOM has been identified as the major cause for membrane fouling and there are conflicting views in the literature. However, some components are clearly implicated. The mechanisms of UF membrane fouling have been shown to be cake formation, pore restriction by adsorption, and pore plugging (see “► [Irreversible Fouling](#)”). Both reversible and irreversible fouling have been found in the membrane treatment of surface waters. Thus, a fraction of NOM with molecular sizes smaller than the membrane pores may adsorb and reduce the pore cross-sectional area for permeation and larger fractions may plug pore entrances or contribute to cake formation.

The hydrophobicity/hydrophilicity of NOM has been found to be a factor influencing membrane fouling in natural water treatment. There is evidence that the hydrophobic components in NOM tend to be responsible for the fouling of hydrophobic membranes due to hydrophobic interactions. However, there are contrary views. In an Australian study, NOM was isolated into four fractions: hydrophilic neutral, hydrophobic acids, transphilic acids, and hydrophilic charged. The

order of the fouling potential of the individual components during MF with PVDF membranes was hydrophilic neutral > hydrophobic acids > transphilic acids > hydrophilic charged. However, it may be that the hydrophilic neutral fraction exhibited the greatest fouling potential because of its size (>30 kD) relative to the membrane pore size. The components of NOM can also be fractionated into the following four fractions by pyrolysis-GC/MS: polysaccharides, proteins, polyhydroxy-aromatics, and amino sugars. It has been found that the fouling potential could be ranked in the order of polyhydroxy-aromatics > proteins > polysaccharides and amino sugars. The polyhydroxy aromatics were thought to be the main foulants for negatively charged NF membrane surfaces, and are probably hydrophobic acids with phenolic groups, exhibiting no negative charge at a neutral pH. However, this could change in the presence of calcium, and similar divalent cations, that appear to exacerbate NF fouling by NOM due to binding between the negative membranes and negative components of the NOM.

Controlling NOM fouling can significantly reduce the cost of membrane water treatment, extend membrane life, and reduce energy demand. Techniques developed to minimize NOM fouling include hybrid membrane processes, pretreatment to reduce the NOM in the raw water, optimization of hydrodynamic parameters, careful membrane selection, and cleaning of the membrane system.

Hybrid membrane processes involve the combination of coagulation/flocculation, or sorbents, such as powdered activated carbon (PAC), heated iron oxide particles (HIOPs), or an ion-exchange resin (such as MIEX[®]) with membrane processes. MIEX[®] is an anion-exchange resin capable of removing relatively low molecular weight negative organics from NOM. It has been shown that using MIEX[®] to remove organics leads to very low fouling of a UF membrane which is hydrophilic and positively charged. The performance was particularly enhanced when calcium was removed. Pretreatment strategies include biologically activated carbon, where a bed of granular carbon with developed biofilms treats the feed water and reduces the biodegradable components of NOM.

Hydrophilic membranes have been found to be less prone to fouling than hydrophobic membranes when treating natural water containing NOM. Unfortunately, most commercially available UF and MF membranes are relatively hydrophobic materials with low surface energies such as polypropylene, polysulfone, polyethersulfone, and polyvinylidene fluoride. Some membranes (such as PVDF) can be rendered more hydrophilic by blending or surface treatment. A recent development involves the use of ceramic UF membranes with ozone pretreatment to oxidize NOM components. This method appears to limit fouling, even at relatively high fluxes.

NaY Membrane for Gas and Vapor Separation

Catia Algieri

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Zeolite membranes owing to their crystalline structure and their pore size at molecular scale allow the continuous separation of gas and liquid mixtures on the basis of diverse molecular size and shape (e.g., isomers azeotropic mixtures) and also on the basis of different adsorption properties (Algieri et al. 2009). High attention was focused on NaY (FAU) zeolite membranes for the separation of CO₂ from light gases. FAU-type zeolite has pore of 0.74 nm and super-cages of 1.3 nm. The change of the Si/Al ratio during the synthesis

permits to obtain FAU zeolite with different adsorption properties, NaX (Si/Al = 1.0–1.5) and NaY (Si/Al > 1.5). NaY membranes, prepared by secondary growth method, exhibited high CO₂/N₂ separation factors (Kusakabe et al. 1997). The prepared membranes were almost defect free. The transport of the molecules took place only through the zeolite pores. The CO₂ passed easily through the zeolite pores being preferentially adsorbed on the wall of the zeolite with respect to the N₂. This behavior occurs because the CO₂ presents a quadrupole moment, while the nitrogen is a nonpolar specie. Hasegawa and coworkers (Hasegawa et al. 2001) prepared exchanged X-NaY membranes (X is K, Rb, and Cs ions) and studied their effect on CO₂/N₂ separation. The experimental results showed highest permeation selectivity with the Rb due to the high sorption selectivity with the Rb-NaY membrane. The results obtained in gas separation process at lab scale are interesting; however, the reproducibility problem during the membrane synthesis and the presence of intercrystalline defects into the zeolite layer hindered the application of these membranes at industrial level. In fact, today, their industrial application is only represented by LTA topology used for the dehydration of different organic solvents by pervaporation or vapor permeation (Morigami et al. 2001). However, LTA topology with a very high aluminum content is stable in a limited range of pH (6.5–7.5). Thus, different research groups studied the application of FAU membranes, more chemically stable than LTA membranes, in pervaporation (PV) or vapor permeation (VP) processes. NaY membranes were used in PV experiments to separate water from ethanol at 75 °C (Sato et al. 2008). Other experiments were performed with ethanol in PV and VP up to 130 °C and 570 kPa. The ethanol fluxes were linearly proportional to the driving force for VP and PV. These performances could be sufficient to use them in the actual industrial permeation processes. Recently, NaY membranes were also used to separate 1,3-propanediol from glycerol and glucose in aqueous solutions. The PV experiments at 35 °C exhibited very high separation selectivity

(1,3-propanediol/glycerol = 80; 1,3-propanediol/glucose = 2400).

n-Butane Dehydrogenation by Membrane Reactor

Ilaria Mirabelli

HyGear B.V. Westervoortsedijk, AV, Arnhem,
The Netherlands

n-Butane dehydroisomerization is a one-step reaction process allowing direct conversion of n-butane to isobutene. It is an alternative to the current isobutene production process by petrochemical cracking and from butane feed (see ► [Dehydroisomerization of N-butane to Isobutene](#)) (Romanow-Garcia et al. 2007; Obenaus et al. 2005). Isobutene is an important intermediate in the petrochemical industry, used as a raw material to produce, for instance, fuel additive (ethyl *tert*-butyl and methyl *tert*-butyl ether) and rubbery materials (polybutene, isoprene). The forecast is for the worldwide demand for isobutene to increase; thus, the interest in

further improving its production is great. Membrane reactor application is an interesting strategy for such dehydrogenative-type reactions, equilibrium limited. A membrane reactor (MR), operating as an extractor, allows removing one of the reaction products from the reaction volume, shifting the equilibrium toward further product production. Moreover, an MR gives the possibility of exceeding the equilibrium constraint of traditional reactors (TRs) improving the conversion achievable and/or lowering the reaction temperature in endothermic, equilibrium-limited reactions of this type (Al-Megren et al. 2013; Marigliano et al. 2003). Yield and selectivity of reaction can be also enhanced, depleting the undesired side reaction. In addition, the MR application, combining the reaction and separation in the same unit, pursues the development and application of integrated processes, as suggested by process intensification criteria (Stankiewicz and Moulijn 2002). Reduction in the equipment number and size, improvement of the process efficiency, and, hence, a better process economy are some of the expected benefits. MRs were investigated, for instance, for the dehydrogenation of ethane, propane, and isobutane, and the authors experimentally demonstrated that conversion of these light hydrocarbons was substantially higher (Alireza et al. 2008; Abashar and Al-Rabiah 2005; Szejner and Sheintuch 2004). In all of these reactions, hydrogen is produced as a coproduct of another valuable chemical. For dehydrogenative-type reactions, H_2 -selective MRs are considered. When these reactions are carried out in an MR, the hydrogen can be removed with high selectivity from the reaction mixture and recovered at high purity directly on the permeation side, as a valuable chemical. Many types of membranes (Sanchez and Tsotsis 2002) have been investigated for this type of application.

Isobutane dehydrogenation using catalytic MRs was studied by a number of researchers (Van den Bergh et al. 2011; Yanglong et al. 2003; Babak et al. 2009).

For example, isobutane dehydrogenation has been studied using γ -alumina, zeolite MFI, palladium/silver and palladium, dense silica, and carbon molecular sieve membranes.

Using a palladium/silver composite MR, increased selectivity and yield with respect to a fixed-bed TR has been obtained (Liang and Hughes 2005). The dehydrogenation of isobutene was studied also in a carbon molecular sieve membrane, achieving 40 % conversion at 500 °C, compared with 32 % at a closed-system equilibrium (Van den Bergh et al. 2011). A thermodynamic analysis carried out on direct conversion of n-butane to isobutene in a membrane reactor, by taking into account simultaneously the chemical reaction and permeative equilibria, showed shift in equilibrium conversion as a result of selective extraction of hydrogen (Al-Megren et al. 2013). The peculiarity in the MR of the selective hydrogen removal allows exploitation of the positive effect of the reaction pressure on the hydrogen permeation and consequently on the conversion, which, on the contrary, in a TR decreases because the reaction occurs with an increase in the number of moles. An MR operating at 500 °C and 20 and 0.1 bar as reaction and equilibrium hydrogen partial pressures, respectively, reaches an equilibrium conversion seven times higher than that obtainable in a TR.

Application of membrane reactor technology to carry on hydrocarbon dehydrogenation reactions allows increasing conversion and yield of dehydrogenated product but also, producing pure hydrogen, adding value to the whole process.

N-Butane Oxidative Dehydrogenation by Membrane Reactor

Miguel Menendez

Department of Chemical and Environmental Engineering, University of Zaragoza, Zaragoza, Spain

Introduction

Butene, isobutene, and butadiene are mainly obtained from steam crackers, but the increased use of natural gas as feedstock has decreased the availability of C4 olefins. Therefore, these olefins are increasingly produced by the dehydrogenation of the corresponding alkane. Since that is an equilibrium-limited reaction, oxidative dehydrogenation has been proposed as an alternative that has raised much interest (Mamedov and

Cortés-Corberán 1995; Madeira and Portela 2002). As it happens in many selective oxidations, the undesired formation of carbon oxides (CO and CO₂) is a serious problem. As in other selective oxidations, membrane reactors have been also proposed for this reaction. Significant improvement of yield has been observed when the oxygen is distributed to a fixed bed of catalyst enclosed in a porous membrane (Téllez et al. 1997). A progressive distribution has been found to be advantageous (Ge et al. 2001). An interesting alternative is the use of CO₂ instead of O₂ as oxidant (Ge et al. 2003). The use of catalytic membrane has also been proposed (Alfonso et al. 2002). Mathematical modeling of those reactors has shown that the reactor performance agrees well with the predictions of mathematical models both for the inert membrane reactor (Téllez et al. 1999) and for the catalytic membrane reactor (Pedernera et al. 2002).

Modifications in the Reactor Configuration

This approach has been employed by several researchers with a variety of modification in the configuration:

- Pure butane in the feed to the bed entry and homogeneous oxygen distribution along the bed using a membrane.
- Butane diluted with inert gas and/or oxygen diluted with inert gas. In comparison with the previous approach, safety is increased and often the achieved selectivity is better, but the industrial application would require the separation of inert gases from the reaction products, increasing the process operation costs.
- Nonhomogeneous distribution of oxygen feed. In order to obtain a greater reaction rate at the reactor entry, a larger permeation of oxygen near the propane entry may be useful.
- Combination of a conventional fixed-bed reactor with a membrane reactor. In such case, the feed to the fixed-bed reactor contains a small amount of oxygen.

- Use of a catalytic membrane. In this case, part of the membrane is loaded with catalyst, preferentially in the side where propane is feed. The operation principle is the same as when a packed bed of catalyst enclosed in a membrane is employed: the lower oxygen partial pressure in the reaction zone increases the selectivity to the desired product.

Types of Membrane

The membrane employed for this reaction does not need to be selective for oxygen, i.e., a mesoporous membrane may be employed. In such case, the back permeation of hydrocarbon to the shell side must be avoided. This usually requires a significant pressure drop of oxygen. Examples of membranes employed include microfiltration ceramic membranes with the pores filled with silica, nanofiltration ceramic membranes with enamel trips to reduce the permeation, or zeolite membranes.

Alternatively dense ceramic membranes, i.e., oxygen selective, can be employed. In such case, in addition to the improvement in butene selectivity provided by the oxygen distribution and the avoidance of back permeation problems, the previous step of oxygen separation from air may be avoided.

Catalysts

Although in principle any catalyst suitable for oxidative dehydrogenation of butane could be tested in a membrane reactor, the most employed are the simplest ones: vanadium oxide supported on alumina or on magnesium oxide.

n-C₄H₁₀/CH₄ Separation

Arnaud Baudot

Physics and Analysis Division, IFP Energies
Nouvelles, Solaize, France

Before treatment, natural gas comes with close to saturation higher hydrocarbons such as ethane, propane, butane, or higher hydrocarbons. It is necessary to remove those compounds for the following reasons:

- Prevent condensation troubles in pipelines: as an illustration, the dew point specification in the US interstate pipeline is fixed at -20°C .
- Propane, butane, or higher hydrocarbons can be valued as liquids and are particularly prized as steam cracker feeds to produce short olefins (ethylene, propylene).
- If the natural gas is used locally as fuel for combustion engines operating compressors or power-generating turbines, the presence of higher hydrocarbons can cause combustion problems or even accelerate aging of the engines.

The conventional technologies used in the industry to remove such “heavies” are condensation or lean oil absorption.

Several companies have been proposing vapor permeation modules to operate heavy hydrocarbon recovery from small natural gas flowstream since the 1990s: *MTR Inc.*, *Borsig*, and *GKSS*. All the membranes in operation are based on silicone-selective layer which offer mixed-gas propane/methane separation selectivity comprised between 3 and 5 (Baker and Lokhandwala 2008; Alpers et al. 1999) and butane/methane separation selectivity ranging from 5 to 10 (Baker and Lokhandwala 2008; Alpers et al. 1999).

NELF Model

Giulio C. Sarti

Department of Chemical Engineering, Mining and Environmental Technology, University of Bologna, Bologna, Italy

The nonequilibrium lattice fluid (NELF) model (Doghieri and Sarti 1996; Sarti and Doghieri 1998) allows to calculate the thermodynamic properties of a solute in a glassy polymeric phase. It represents the suitable extension to the nonequilibrium glassy phase of the equilibrium lattice fluid equation of state by Sanchez and Lacombe (1976, 1978) and Lacombe and Sanchez (1976), according to the general rules of the nonequilibrium thermodynamics for glassy polymers (NET-GP) (Doghieri et al. 2004a, 2006; Giacinti Baschetti et al. 2005a), which requires in general that the state of a isotropic homogeneous glassy phase is given by temperature T , pressure p , densities of all solutes ρ_i , and density

NELF Model, Table 1 List of symbols and properties used in the NELF model

	Symbol	Name	Definition/property
Pure component i	ρ_i^*	Characteristic density of pure component i	
	p_i^*	Characteristic pressure of pure component i	
	T_i^*	Characteristic temperature of pure component i	
	r_i^0	Number of lattice sites occupied by a mole of pure component i	$r_i^0 = \frac{M_i}{\rho_i^* v_i^*}$
	v_i^*	Volume occupied by a mole of lattice sites of pure substance	$v_i^* = \frac{RT_i^*}{p_i^*}$
Mixtures	N	Total number of moles	
	T	Temperature	
	p	Pressure	
	ρ	Density	
	ρ_i	Density of species i	$\rho_i = \omega_i \rho$
	ρ_{pol}	Density of polymer species	$\rho_{pol} = \omega_{pol} \rho$
	ω_i	Mass fraction, $i = 1, 2, \dots, N_p$	$\omega_i = \frac{\rho_i}{\rho}$
	ϕ_i	Volume fraction	$\phi_i = \frac{\omega_i / \rho_i^*}{\sum_i \omega_i / \rho_i^*}$
	ρ^*	Characteristic density of the mixture	$\frac{1}{\rho^*} = \sum_i \frac{\omega_i}{\rho_i^*}$
	p^*	Characteristic pressure of the mixture	$p^* = \sum_i \phi_i p_i^* - \frac{1}{2} \sum_i \phi_i \sum_{j \neq i} \phi_j \cdot \Delta p_{ij}^*$
	Δp_{ij}^*	Binary parameter	$\Delta p_{ij}^* = p_i^* + p_j^* - 2(1 - k_{ij}) \sqrt{p_i^* \cdot p_j^*}$
	k_{ij}, Ψ_{ij}	Dimensionless binary parameter	$\Psi_{ij} = 1 - k_{ij}$
	r	Molar average number of lattice sites occupied by a molecule in the mixture	$r = \sum_i x_i r_i$
	T^*	Characteristic temperature of the mixture	$T^* = \frac{v^*}{r} \sum_i x_i r_i^0 \frac{T_i^*}{p_i^*} = \frac{v^* v^*}{R}$
	ε^*	Characteristic energy	$\varepsilon^* = \frac{T^*}{k}$
	v^*	Average close-packed mer molar volume in the mixture	$v^* = \frac{RT^*}{p^*}$
	$\tilde{\rho}$	Dimensionless density	$\tilde{\rho} = \frac{\rho}{\rho^*}$
	$\tilde{T}$	Dimensionless temperature	$\tilde{T} = \frac{T}{T^*}$
	$\tilde{p}$	Dimensionless pressure	$\tilde{p} = \frac{p}{p^*}$
	A^{Eq}	Total equilibrium Helmholtz free energy	$\frac{A^{Eq}}{rNR T^*} = -\tilde{\rho} + \tilde{T} \left[\left(\frac{1}{\tilde{\rho}} - 1 \right) \ln(1 - \tilde{\rho}) + \frac{1}{\tilde{r}} \ln(\tilde{\rho}) + \sum_{i=1}^{N_p+1} \frac{\phi_i}{r_i} \ln(\phi_i) \right]$
	μ_i^{NE}	Chemical potential of solute i in the nonequilibrium glass	$\frac{\mu_i^{(S)}}{RT} = \ln(\tilde{\rho} \phi_i) - \left(r_i^0 + \frac{r_i - r_i^0}{\tilde{\rho}} \right) \cdot \ln(1 - \tilde{\rho}) - r_i - \tilde{\rho} \frac{r_i^0 v_i^*}{RT} \left[p_i^* + \sum_{j=1}^{N_p} \phi_j (p_j^* - \Delta p_{ij}^*) \right] + 1$

of the polymer species ρ_{pol} (polymer mass per unit volume of the mixture). The latter quantity is the value prevailing in the nonequilibrium state of the glass, at the temperature, pressure, and composition considered; it depends on the thermomechanical prehistory of the polymer phase and is due to the kinetic hindrance offered by the glassy phase which does not allow the polymer density to reach the value minimizing Gibbs free energy at the given T and p. Polymer density must be assigned as additional nonequilibrium state variable, e.g., on the bases of direct experimental or other equivalent information; it represents the departure from

the equilibrium of the glassy phase and is formally treated as an internal state variable (Sarti and Doghieri 1998). From the general results of NET-GP (Doghieri et al. 2004a, 2006; Giacinti Baschetti et al. 2005a), the Helmholtz free energy of the glassy phase is formally given by the same expression of the equilibrium Helmholtz free energy, as a function of T, ρ_i , and ρ_{pol} , where the latter is a nonequilibrium value.

The most relevant result of the model is embodied by the following explicit expression of the chemical potential of each solute *i* in the glassy mixture, as a function of temperature, composition, and polymer density:

$$\begin{aligned}
 \frac{\mu_i^{(S)}}{RT} = & \ln(\tilde{\rho}\phi_i) - \left(r_i^0 + \frac{r_i - r_i^0}{\tilde{\rho}} \right) \\
 & \cdot \ln(1 - \tilde{\rho}) - r_i \\
 & - \tilde{\rho} \frac{r_i^0 v_i^*}{RT} \left[p_i^* + \sum_{j=1}^{N_p} \phi_j (p_j^* - \Delta p_{ij}^*) \right] + 1
 \end{aligned}
 \tag{1}$$

The quantities used by the model are defined in Table 1. The model expressions contain pure component parameters and one binary interaction parameter for each couple of components in the mixture. The pure component parameters for the polymers are obtained from volumetric data above the glass transition temperature (Doghieri

and Sarti 1996; Sarti and Doghieri 1998); alternative techniques have been proposed for the polymers degrading before glass transition is reached (Galizia et al. 2012). The pure component parameters for gases are obtained from volumetric data; for vapors and liquids, vapor pressure data are also used.

A collection of pure component parameters for polymers of interest in membrane separations is reported in Table 2, while for relevant penetrants, pure component parameters are reported in Table 3. The binary interaction parameters are generally used as fitting quantities, even though a predictive method has been proposed (Rodgers and Sanchez 1993), and often the first order approximation of $k_{ij} = 0$ is also acceptable. Remarkably, the nonequilibrium model, using T and ρ_{pol} as input, is much less sensitive to the binary parameter than the corresponding equilibrium model, using temperature and pressure as input.

The phase equilibrium (or more properly pseudo-equilibrium) conditions between the glassy nonequilibrium phase and an external fluid phase, either gaseous or liquid, are represented as usual:

$$\mu_i^{(S)} = \mu_i^{(\text{external fluid})} \quad (2)$$

By using Eq. 1 for the chemical potential of species i dissolved in the glassy phase and usual equilibrium expression for the chemical potential of species i in the external fluid phase, from Eq. 2 one obtains solubility isotherms for pure penetrants (Doghieri and Sarti 1996, 1998; Sarti and Doghieri 1998; Giacinti Baschetti et al. 2001; De Angelis et al. 2007) as well as for mixed gases (Doghieri et al. 2004b; Minelli et al. 2011), in pure glassy polymers, in polymer blends (Grassia et al. 2004), as well as in glassy-mixed matrices (Maria Grazia De and Sarti 2008; Maria-Chiara et al. 2010). The model is also suitable to calculate the solubility of liquids in glassy polymers (Sarti and De Angelis 2012).

Whenever the binary interaction parameters are known from data above the glass transition

temperature, and polymer density is known, the model is entirely predictive (Doghieri and Sarti 1996; Sarti and Doghieri 1998). Under non-swelling conditions the polymer density remains equal to the value of the pure unpenetrated polymer (Doghieri and Sarti 1998; Giacinti Baschetti et al. 2001). At high pressures and for swelling penetrants, volume dilation of the polymers is required, e.g., through the use of a swelling coefficient (Giacinti Baschetti et al. 2001). Remarkably, the model also shows that in all cases, both at low and high free volume, it is sufficient to consider only molecules dissolved in the glassy phase, without the need of an arbitrary differentiation between hypothetically different populations of penetrant molecules.

The interested users can freely download the code for the solubility isotherms of binary mixtures (<http://serwebdicma.ing.unibo.it/polymers/index.htm>).

Synonyms

Neuronal tissue regeneration

The expression “neuronal regeneration” refers to all the strategies available for the regrowth, repair, or the substitution of neuronal cells or cell products after an injury causing damages and/or degeneration of the nervous system (NS). In higher organisms like animals and human beings, the regenerative ability of the nervous system is very limited. The NS consists of two connected sections called central and peripheral systems. The central nervous system (CNS), in charge of the behavior control and the information processing, includes the brain and the spinal cord, whereas the peripheral nervous system (PNS) is made up of cranial, spinal, and autonomic nerves, able to coordinate locomotion, sensory perception, and homeostasis. Intended for the transmission and the report of signals and information between the body and the brain, the

neurons are the main units for both the systems, but due to the different glial cell composition, a discrepancy between the regenerative capabilities in the central nervous system and the peripheral nervous system is recorded. Glia is constituted of nonneuronal cells serving to provide physical and chemical support and protection to neurons. Schwann cells and oligodendrocytes are respectively the main glia components of the PNS and the CNS. They are responsible of the axons myelination allowing rapid and efficient signal transmission and impulse conduction between the two systems, whereas the central astrocytes serve the maintenance of the homeostasis and the recycle of the neurotransmitters. When an injury occurs and the peripheral axons are severed, leading to the Wallerian degeneration, macrophages and monocytes migrate in the injured site to remove myelin and axon debris. Schwann cells proliferate in order to substitute glial cells lost during injury and initiate the production and secretion of laminin and fibronectin, which provide the path for the regeneration. Moreover, they upregulate the expression of adhesion proteins (NCAMs), cadherins (N-cadherin), and other neurotrophic factors (BDNF, CNTF, GDNF) involved in the axonal regeneration across the area of injury and lead the formation of growth cones in the proximal damaged axons. Unlike peripheral glia, oligodendrocytes in the CNS are not able to proliferate, and then cells lost to injury are not replaceable. Furthermore, the growth-promoting activity of the central glia is not enough to ensure the conductive environment for the axonal regrowth due to the over expression of inhibitor factors of the axon growth. After a trauma or an injury, the production of neuroprotective factors is quite limited and eventually not enough to oppose the two main mechanisms occurring in the central nervous system. First, the apoptotic phenomena affecting the surrounding of the damaged area over a great distance, due to the secretion of members of the transforming growth factor family (TGF) that largely promote cell death. Secondly, the proliferation of glial cells in quiescent state and the consequent formation of a glial scar acting as physical barrier for the axonal regeneration. Astrocytes actually produce and secrete specific

factors, such as NOGO proteins, NI-35, chondroitin sulfate proteoglycans, and keratan sulfate proteoglycans, known to be inhibitors of the remyelination and axon repair (Steward et al. 2013; Allodi et al. 2012). Then, the modulation of the regenerative process in the nervous system lies on different approaches depending on the site and the extension of the injured area. Independently on the causes, an injury affects the nervous system with the inability of neuronal cells to transmit impulses to specific regions of the nervous system. In order to restore the functionalization, one of the three specific repair mechanisms must occur: the regrowth of the neuronal damaged axons, the recovery of the axonal function, or the substitution of the neurons that have been lost through the generation of new neuronal cells. Each one of these regenerative methods stands as alternative to the gold standard treatments, represented by the coaptation and the nerve graft implantation. The first one consists in the surgical reparation of small nerve gap (<8 mm) resulting after an injury, and the second one consists in the implantation of grafts regardless the size of the gaps. Generally autografts, which have no risk of immune reactions, are the first choice in the nerve injury treatment, but allografts and xenografts are also available. Therefore, none of them allow to reach a full functional recovery and many drawbacks are possible.

Cell Replacement or Cell Therapy. When a wide area of the nervous system has been damaged by a trauma or a degenerative pathology, a replacement of the neuronal cells can be obtained using stem cells. Neural stem cells (NSC) are available from the hippocampus, spinal cord, fetal brain, and neural retina and due to the ability to self-renew can differentiate in neurons, astrocytes, and oligodendrocytes in order to substitute cells lost in the injury. Amyotrophic lateral sclerosis (ALS), spinal muscular atrophy (SMA), main motor neuron disorders, and Parkinson's disease (PD) are the focus of the neural stem cell strategies. NSC not only can be integrated into host nervous system but also have been engineered to act as delivery vehicle for neuroprotective growth factors like the GDNF

and IGF-1, resulting in an increase of the spinal motor and the dopaminergic neuron survival (Tysseling and Kessler 2011). Pluripotent stem cells have been also successfully used as strategy for the neuronal regeneration. They represent a perfect in vitro system for developmental studies and can be not only differentiated in neurons but reprogrammed to form stem cells facilitating the replacement of degenerated neurons from autologous sources avoiding grafts rejection in the patients (Steward et al. 2013).

Drug Delivery. Many natural and synthetic molecules have shown to possess neuroprotective and neurogenerative properties. The administration of neurotrophic factors demonstrated an improvement of the regenerative process in both the central and the peripheral nervous systems. The intact blood-spinal cord barrier represents an obstacle in reaching the brain and the spinal cord, but generally after injuries or degenerative processes, several parts result to be compromised; therefore, neurotrophins and drugs administered can overcome the barrier reaching the site of action. Carrier, microcarrier, microspheres, liposomes, and hydrogels are the devices available for the controlled release, and synthetic or natural polymers, extracellular matrix derived biomaterials, carbon nanoparticles, and ions complexes represent only a few of the biomaterials usable for their preparations (Tysseling and Kessler 2011; Gu et al. 2014). Moreover, not only spinal cord and nerve regeneration have been achieved, but due to this strategy central diseases such as Parkinson's and Alzheimer's are possible. In fact, the controlled release of dopamine and β -amyloid inhibitors represents today the best treatment available for the neurodegenerative pathologies in combination with the cell transplantation. Moreover, in order to avoid multiple drug injections and to increase the delivery time in the selected area, mini-pumps are available and surgically implantable in patients for the treatment of the chronic pain and the degenerative diseases.

Nerve Conduit, Scaffolds, and Channels. The protection of the injured site from inhibitor factors and apoptotic/inflammatory phenomena is of

main importance in order to increase the regenerative process in the nervous system. This is the reason why scaffolds, channels, and conduits have been purposely made to protect the severed areas during the regeneration and tested in in vitro and in vivo studies. With the aim of recreating a permissive environment for the neurite and axonal growth, these synthetic devices consisting of polymers and hydrogels in form of tubes or fibers possess morphological, chemical-physical, and mechanical specific properties. Topography, mechanical strength, biodegradation, porosity, and dimensions are necessary to induce cell adhesion, proliferation and differentiation, to allow the nutrient and growth factor supply, to remove the metabolites and inhibitors, and to avoid the device collapsing during the regenerative process after the implantation (Sedaghati et al. 2014; Morelli et al. 2010). Collagen, laminin, fibronectin, polycaprolactone, polylactic acid, and chitosan tubes are allowed to build high-quality guides for the neural repair. In addition, in the last decade, the nerve conduits have been further developed and leveled up through the combination with supportive cells and the growth factors incorporation. Alternatively, neural stem cells and pluripotent cells are seeded in the lumen of the tubes, and they stimulate the release of diffusible growth factors in order to induce the neurite outgrowth and axonal regeneration in the insulated area. On similar lines of the drug delivery, growth factors and neuroprotective agents are encapsulated in the scaffolds or incorporated in the biomaterials and then let diffuse towards the severed site. This new approach increases the neural regeneration guiding the axonal growth in both the central and peripheral nervous systems.

Despite the autografts still remain the gold standard for the treatment of the nervous system injuries, the promising results recorded in the biomaterials field represent the best alternative in the development of new regenerative approaches, based on the controlled drugs and factors release, the guidance of the axonal regrowth, and the transplantation of cells in the selected area.

NF Membrane Characterization Methods

Paul Melvyn Williams
College of Engineering, Swansea University,
Swansea, UK

A variety of techniques and approaches are routinely used for characterizing the physical and chemical properties of nanofiltration (NF) membrane surfaces (Web Report #4102 2012). The main fundamental properties which are usually characterized, in no particular order, include molecular weight cut-off (MWCO), pore size (and pore-size distribution), pure water flux, surface charge (or zeta potential), hydrophobicity and/or hydrophilicity, and membrane morphology and surface roughness.

The molecular weight cut-off is found by filtering a range of molecules (very often polyethylene glycol (PEG)) with known molecular weights. The molecular weight of the molecule that is 90 % retained by the membrane is usually defined as the MWCO of that membrane.

The pore size of the membrane may be found via atomic force microscopy (AFM) measurements or more usually by filtering an uncharged molecule like glucose and fitting the Nernst-Planck equation for uncharged solutes to the results, using the membrane pore size as the fitting parameter. NF membranes are typically rated by MWCO rather than nominal pore size.

The flux or pure water flux for a membrane is typically expressed as volume per area per unit of time. Flux is used to express the rate at which pure water permeates a NF membrane. Typical units of measurement are gallons per square foot per day (i.e., GFD or GSFD) or liters per square meter per hour ($\text{l/m}^2/\text{h}$)

Streaming potential measurements are most often used to calculate the zeta potential of an NF membrane surface. This is an indicator of the membrane surface charge under variable solution chemistries.

Measuring the contact angle that is formed when a droplet of water is placed on the membrane surface is used to quantify the hydrophobicity/hydrophilicity of the membrane surface.

AFM and scanning electron microscopy (SEM) are both powerful techniques used to quantify and visualize the morphology or roughness of membrane surfaces. SEM in particular is used to visualize the cross-sectional morphology of NF membranes.

Nichel Recovery by Liquid Membrane

Pietro Argurio

Department of Environmental and Chemical Engineering, University of Calabria, Arcavacata di Rende, Italy

Heavy metal removal from various industrial wastewaters is a major concern, since they are often present at significant levels. Among the numerous industrial sectors that contribute to environmental pollution with these metals, such as dyeing, mining, electroplating, nuclear power operations, aerospace, and battery manufacturing processes, the metal finishing industry is very important due to the large number of locations as their geographical dispersion. Heavy metals differ from organic substances because they are not biodegradable (Lothongkum et al. 2009). Thus, they can accumulate in living tissues, causing various diseases and disorders, since they are toxic to human beings and organisms even at very low concentrations (Hassaine-Sadi et al. 2012). Among these metals, chromium, nickel, zinc, copper, and cadmium are the most abundant ones.

The main way of water contamination by heavy metals is the discharge of liquids effluent with relatively low but harmful concentration. As a consequence, the appropriate treatment of high-volume wastewater containing low concentrations of heavy metals is very important, and in addition, the discharge regulation is progressively becoming more stringent. The World Health Organization recommends the toxic limits of permissible concentration of Ni in wastewaters at a level of 1 mg/L as insoluble compounds, 0.1 mg/L as soluble compounds, 0.05–0.12 mg/L as nickel carbonyl, and 1 mg/L as nickel sulfide. Many countries have regulations of the maximum

permissible concentration of nickel in industrial wastewaters with values in the order of 1 mg/L.

Chemical precipitation is extensively used to treat nickel-bearing wastewater, resulting in the production of a large amount of toxic chemical sludge which disposal/treatment is a very costly affair, and it is not eco-friendly (Molinari et al. 2009). Other convectional methods, such as filtration after neutralization, ion exchange, and adsorption, are not selective, and thus, no metal recovery is achieved. Besides, they are expensive methods and not efficient enough to reduce nickel concentration below the permissible concentrations.

Transport of metal ions across a liquid membrane (LM) is a powerful technology combining extraction and stripping into a one-step process (Güell et al. 2008; Walkowiak and Kozłowski 2009). LM systems include bulk liquid membrane (BLM), emulsion liquid membrane (ELM), and supported liquid membrane (SLM). The lower capital and operating costs, the low energy and extractant consumed, and the high selectivity are the main advantages of LM systems with respect to the traditional separation techniques. Thanks to these characteristic, LM-based techniques permit to obtain the recovery of heavy metal ions and the production of water with good quality, resulting into both environmental and economic benefits.

The selective separation of nickel from various aqueous media containing nickel and cobalt, that is, an important problem in hydrometallurgy, can be carried out by using ELM (Longquan et al. 1997; Kumbasar and Tutkun 2008). Ni and Co possess aqueous similar chemical behavior, because they are metal of the transition series adjacent in the periodic table, but some differences exist. In ammoniacal environment (Kumbasar 2009) the complex $\text{Co}(\text{NH}_3)^{2+}$ is readily oxidized to $\text{Co}(\text{NH}_3)^{3+}$ with addition of hydrogen peroxide, while the nickel complex $\text{Ni}(\text{NH}_3)^{2+}$ is not oxidized. In these conditions the nickel ammine complex can be selectively extracted using an acidic extractant (e.g., 5,7-dibromo-8-hydroxyquinoline (DBHQ)) by the following reversible pH-dependent reaction:

The concentration of complexing agent (e.g., ammonia) in the feed phase, the pH of the feed and of the strip aqueous phases, the composition of the LM phase (extractant concentration, surfactant concentration, modifier concentration), the mixing speed of feed solution, the presence of complexing agent and its concentration in the strip phase, and the feed/strip volumetric ratio are the most important operating variables influencing the permeation of nickel across a LM and then membrane selectivity.

The selective recovery of nickel ions from wastewater of stainless steel manufacturing plants can be efficiently carried out by hollow fiber supported liquid membranes (HFSLM). The type of extractant and its concentration in the LM phase, the pH of the feed phase, the stripping solution concentration (i.e., pH), the flow rates of feed and stripping solution, and the volumetric ratio of feed to stripping solutions represent the most important parameters affecting system selectivity (Lothongkum et al. 2009). Two or more HFSLM modules can be placed in series, obtaining satisfactory nickel recovery and an aqueous effluent with concentration within the common permissible limits.

Gujarat, India

Recovery of nickel from aqueous effluents by membrane operations.

Nickel, combined with other elements, occurs naturally in the earth's crust, and the earth's core is composed of 6 % nickel. It is found in all soil and is also emitted from volcanoes. Pure nickel is a hard, silvery-white metal. It has properties which make it a favored alloy. The nickel alloys are used in making metal coins, jewelry, and industry. Most nickel is used to make stainless steel. It is added to metals to increase their hardness, strength, and corrosion resistance. Nickel forms compounds with many elements including chlorine, sulfur, and oxygen. Most of these nickel compounds are fairly water soluble. Nickel and its compounds have no characteristic odor or taste. Nickel compounds are used for nickel plating, to color ceramics, to make some batteries, and as catalysts that increase the rate of chemical reactions. Nickel is released into the atmosphere during nickel mining and by industries that make or use nickel, nickel alloys, or nickel compounds. These industries also might discharge nickel in wastewater. Nickel is also released into the atmosphere by oil-burning

Fig. 1 Percentages of extraction and recovery of nickel ions from a single-module and double-module operations at different concentration of LIX 860-I: pH of feed solution = 4, stripping solution $[\text{H}_2\text{SO}_4] = 1.5 \text{ M}$ (single module) and 2.0 M (double modules), $Q_{\text{feed}} = Q_{\text{strip}} = 100 \text{ mL/min}$, and $V_{\text{feed}}:V_{\text{strip}} = 3500:3500 \text{ mL}$ (Reproduced with permission from Elsevier)

power plants, coal-burning power plants, and trash incinerators (Toxicological Profile for Nickel 2013).

Nickel is removed from electroplating wastes by treatment with hydroxide, lime, and/or sulfide to precipitate the metal (HSDB 2004). Nickel is removed/recovered from various wastes, such as spent solutions, spent batteries, spent Ni–Cd

batteries, spent Ni–MH batteries, spent catalysts, waste electrical and electronic equipment by chemical precipitation, ion flotation, ion exchange, membrane filtration, adsorption, crystallization, solvent extraction, electrodialysis, electrowinning, and pyrometallurgical and hydrometallurgical techniques (Coman et al. 2013). The removal efficiency of nickel by some membrane

separation methods is shown in Table 1 (Coman et al. 2013). Eisenmann (1981) observed that the electrodialysis (ED) can concentrate the nickel 50- to 100-fold than that of reverse osmosis, and ED is better than the ion exchange system. Castelblanque and Salimbeni (2004) reported recovery of nickel from cleaning baths in the electrodeposition of nickel by NF and RO with encouraging results. The recovery of nickel from stainless steel cold-rolled plate process by hollow fiber-supported liquid membrane (HFSLM) with the help of extractants di(2-ethylhexyl) phosphoric acid (D2EHPA), bis(2,4,4 trimethylpentyl) phosphinic acid (Cyanex 272), bis(2,4,4 trimethylpentyl) dithiophosphinic acid (Cyanex 301), and 5-dodecylsalicylaldoxime (LIX 860-I) gave fruitful results (Lothongkum et al. 2009). Lothongkum et al. (2009) found that the nickel recovery with a single-module operation was 58 %, whereas by double-module operation recovery reached 87 % using the LIX 860-I extractant (Fig. 1). Researchers showed (de Voorde et al. 2004; Darvishi et al. 2005) that the synergistic effect of the combination of the extractants was more than that when the extractants are used separately. The extractant di-2,4,4-trimethylpentyl mono-thio-phosphinic acid (Cyanex 302) was found to be more suitable than the other in the recovery of nickel (Darvishi et al. 2005; Dimitrov et al. 2008).

Niobium (Nb), Vanadium (V), and Tantalum (Ta) Alloys, Membranes of

Ekain Fernandez

Energy and Environment, TECNALIA, Donostia-San Sebastian, Gipuzkoa, Spain

Niobium (Nb), vanadium (V), and tantalum (Ta) are the so-called refractory metals, and they have much higher hydrogen permeability at temperatures below 300 °C in comparison to palladium as shown in Fig. 1. These metals are much cheaper and have greater tolerances to high temperatures compared to palladium (Gallucci et al. 2013). Therefore, studies on replacement of Pd by these metals and their alloys have increased during the last years (Mundschau et al. 2006).

General Aspects

These membrane materials have two main drawbacks: they are easy to oxidize and are not able to dissociate and recombine hydrogen molecules. The most used catalytic materials to be coated on the surface of the refractory materials in order to enable hydrogen transport are Pd, Pt, Ni, Rh, Ir, Co, and alloys thereof (Dye and Snow 2001). The

Niobium (Nb), Vanadium (V), and Tantalum (Ta) Alloys, Membranes of, Fig. 1 Hydrogen permeability through several metals as a function of temperature (Basile et al. 2008)

thicknesses of these catalytic layers are usually in the order of hundreds of nm, and thus the cost of using a noble metal instead of Pd does not contribute significantly to whole cost of the membrane. Pure niobium, vanadium, tantalum, and also Zirconium have very high permeabilities, but they are also very brittle. On the contrary, several alloys of these metals are also non-embrittling, making them good candidates for hydrogen purification membranes (Yang et al. 2006; Dolan 2010; Dolan et al. 2011; Ishikawa et al. 2011; Paglieri et al. 2011; Wolden et al. 2013).

Niobium, Vanadium, and Tantalum Alloys

According to Yukawa et al., V-based alloys expect to possess stronger resistance to hydrogen embrittlement than Nb-based alloys (Yukawa et al. 2011). When the composite membranes work at elevated temperature ($>400^\circ\text{C}$), the diffusion between the core component and the catalytic layer may occur, causing oxidation of the core metal and a resulting hydrogen permeability

reduction (Behr et al. 1988). Behr et al. recommend the use of Pd-Cu, Pd-Ag, and Pd-Y catalytic layer with Nb, Ta, Ti, and V core metals saturated with Cu, Ag, or Y in order to reduce the driving force for interdiffusion (Behr et al. 1985). Another approach is to use interdiffusion barrier layers, such as oxides, sulfides, and selenides (Dye and Snow 2001; Edlund and McCarthy 1995). And another approach is to use an alloy component that has catalytic activity. Hara et al. proposed ZrNi alloy where Ni acts as the catalytic part and Pd-based layer is not needed (Hara et al. 2002). Another important problem working at high temperatures is that the thin catalytic layer may be delaminated from core membrane due to the difference in thermal expansion coefficient of each part. Mundschau et al. defined the mismatch of thermal expansion coefficient of Pd in comparison to V, Ta, Nb, and Zr at different temperatures, and Pd-V composite membrane has the best match of thermal expansion coefficient (Mundschau et al. 2006). Many amorphous alloys crystallize at high temperatures (over the crystallization temperature (T_x) or glass transition temperature (T_g) of the alloys) and lose the properties that they have as amorphous structures (Dolan

et al. 2006). This is the case of Zr-based alloys that have a T_g around 550–600 °C and are not suitable for high-temperature hydrogen separation. Finally, the resistance to poisoning (e.g., with sulfur) depends mainly on the nature of the deposited catalytic layer, so if the whole membrane has to resist a specific sulfur content, a suitable Pd alloy layer should be chosen (Mundschau et al. 2006).

Membrane Preparation

The most common techniques for the preparation of the refractory metal (Nb, V, Ta, Zr) alloy membrane preparation are rolling and melt spinning (Dolan 2010). Films of above 30 μm -thick films are prepared using these techniques. Then, Pd-based alloy thin catalytic layers are needed on both surfaces of the refractory metal, and other thin film deposition techniques are used such as physical vapor deposition. The future membranes should be composed of thinner refractory membranes and should be supported on porous supports as in the case of palladium-based membranes.

Membrane Commercialization

REB Research and Consulting produces and offers refractory metal-based tubular membranes: tantalum- and niobium-based membranes coated with Pd.

NOM-Based Membrane Fouling

Raymond L. Legge

Department of Chemical Engineering, University of Waterloo, Waterloo, ON, Canada

Definition

NOM or natural organic matter is the complex mixture of organic material that can be found in surface or groundwater and can contribute to one form of membrane fouling by accumulating on the surface and/or in the membrane pores resulting in reduced permeate flux or fouling.

Overview

Various fractions in natural organic matter (NOM) and particulate/colloid matter (C/P) are known to significantly contribute to fouling of ultrafiltration (UF) membranes. NOM originates through contact of the water with dead and living organic matter. These components may contribute in different ways to fouling and may require different approaches for membrane regeneration. Fouling may be reversible or irreversible, and this will depend not only on the chemical and physical properties of the membrane (e.g., molecular weight cutoff (MWCO)), but also the configuration of the membrane system (e.g., flat sheet vs. hollow fiber) and other factors such as the nature of the upstream treatment, membrane flux, flow regime, and filtration time. Interaction of the NOM components may also have an influence on the fouling, and this may depend on whether the interaction occurs in the water matrix or at the level of the membrane as the fouling occurs or both. Interactions are not restricted to NOM components but can also occur between other components in the water matrix, such as divalent cations. Broad classification of the NOM constituents would identify the biopolymer fraction, which includes proteins, polysaccharides, and humic substances. Another concern related to NOM, as it pertains to drinking water,

is that reactions between NOM and the commonly used disinfection agent chlorine can result in the formation of disinfection by-products which have been identified as possible carcinogens.

Noncellulosic Membranes

Hongyang Ma, Benjamin S. Hsiao and

Benjamin Chu

Department of Chemistry, Stony Brook University, Stony Brook, NY, USA

Noncellulosic membrane is a membrane system without any cellulosic units. Typical noncellulosic membranes include inorganic membranes, synthetic polymer membranes, and natural polymer (excluded cellulosic materials) membranes. One type of inorganic membrane, which contains zeolite, has been used in reverse osmosis, ultrafiltration, and pervaporation (Ulbricht 2006). Synthetic polymer membranes include membrane systems applied over a broad range of the filtration spectrum from microfiltration to reverse osmosis. Representative synthetic polymer membranes for microfiltration and ultrafiltration membranes include polyacrylonitrile (PAN), polysulfone (PSU), polyethersulfone (PES), and polyvinylidene fluoride (PVDF) (Ma et al. 2012). The barrier layer in synthetic polymer membranes for nanofiltration and reverse

osmosis applications typically consists of highly cross-linked polyamide made by interfacial polymerization (Petersen 1993). Natural polymer membranes include protein membranes and noncellulosic polysaccharide membranes, consisting of different sugar units. Selective examples include silk membranes fabricated by electrospinning and chitin (chitosan) composite membranes (Ma et al. 2011a; Yoon et al. 2006; Ki et al. 2007).

The development of cellulosic membranes occurred relatively earlier than that of non-cellulosic membranes (Edgar et al. 2001). Noncellulosic membranes have achieved higher filtration efficiency and durability when compared with those of cellulosic membranes. For example, noncellulose membranes exhibit high chemical resistance and pH tolerance by avoiding the disadvantages of cellulosic membranes composed of glucose units linked with ether bonds (Chenoweth 1986). However, low cost has always been the merit of cellulose and cellulose derivative membranes.

With the introduction of nanotechnology, nanocomposite membranes have overcome many of the obstacles in membrane quality, including higher flux and lower fouling rate. Natural and synthetic, inorganic and organic, and cellulosic and noncellulosic materials can be integrated together to enhance the membrane performance and retain cost-effectiveness. Therefore, nanocomposite membranes are likely the direction in future filtration applications (Ma et al. 2011b).

Noncovalent Binding for Polymer Surface Modification

Teresa Poerio

Institute on Membrane Technology, National Research Council of Italy, ITM–CNR, Rende, Italy

The polymer surface modification by non-covalent binding is obtained by electromagnetic interactions between molecules that can be generally classified into ionic interactions, hydrogen bond, and van der Waals forces. The surface modification through van der Waals attraction and/or hydrogen bonding is a simple method to improve membrane surface properties. The surface modification by non-covalent binding is obtained by coating. Coating a membrane surface with a thin layer of polymers or surfactants permits to optimize hydrophilicity, smoothness, and surface charge of the membrane surface. Thus, the surface-modified membranes have better performance and antifouling characteristics than the base membranes. Many hydrophilic polymers, such as PVA, PAA, PEG-based hydrogels, and chitosan have been coated on different MF, UF, NF, and RO membranes using casting, adsorption, or filtration techniques. The first studies in the field of the membrane coating concerned the modification of UF membranes to reduce their fouling with proteins (Nystrom 1989).

In the casting technique, a polymer is casted on the membrane and then the coated membrane is immersed in the coagulation bath to have the precipitation of the polymer. Asatekin (Asatekin et al. 2009) prepared novel composite NF membranes by casting of the synthesized amphiphilic copolymer PAN-graft-poly(ethylene oxide) (PAN-g-PEO) on UF PAN membranes.

In the case of the adsorption techniques, the membrane surface is modified putting in contact the membrane with a solution of different polymer, and then after solvent evaporation, a thin film of a different polymer forms a new surface. The adsorption can occur on the surface and inside the pores on the pore walls. Maartens (Maartens et al. 2002) used the adsorption of the nonionic surfactants Triton[®] X-100 and Pluronic[®] F108 for the surface modification of tubular UF PES membranes, which were used for filtering the pulp and paper effluents. Triton[®] X-100 is adsorbed to the membrane by hydrophobic interaction with hydrophobic C₆H₄ group. Ba et al. (2010) used the adsorption of water-soluble polymers such as PVA, poly-acrylic acid (PAA), and polyvinyl sulfate-potassium salt (PVS) on the surface of the positively charged P84-PEI membrane to form a protective coating layer to improve membrane fouling resistance.

In the filtration technique, the surface modification is obtained by filtration of a solution containing the polymer. PVA-coated thin film composite (TFC) membranes were obtained by filtration of aqueous solutions containing PVA and cross-linking agents through the porous membrane support, followed by heat treatment (Liu et al. 2000). A PVA gel layer was formed on the surface and in the pores of the modified membranes. The modified membranes showed higher antifouling properties with respect to the unmodified membranes during UF of the pepsin solutions. The UF PES membranes containing negatively charged sulfonic acid group on the surface were obtained by filtration of an aqueous solution of poly(sodium 4-styrenesulfonate) (PSS) for about 100 min using a dead-end filtration cell (Reddy et al. 2003).

A new coating method based on supramolecular assembly very suitable for membrane surface modification is layer-by-layer (LBL) technique

(Decher 1997) in which the assembly is obtained by means of alternative adsorption of linear polycations and polyanions. This technique not only creates a charged skin layer but also allows for a better control of the thickness, charge density, and hydrophilicity of the active skin layer. The only condition for the use of the self-assembly method is that the base membrane must be able to adsorb the first polyelectrolyte layer by means of ionic bonds.

The membrane modified by non-covalent binding is employed in ultrafiltration process as antifouling membrane (Luo et al. 2005) in gas separation process to improve membrane separation performances (Widjojo et al. 2007), in the vapor separation of a wide variety of volatile compounds (Zhen et al. 2006). Indeed, the PVDF hollow-fiber membrane coated with PDMS exhibited very high removal efficiency (>90 %) for all the following VOCs, benzene, chloroform, acetone, ethyl acetate, and toluene. However, despite the flexibility surfaces modification by non-covalent binding interactions to change the hydrophilicity, smoothness, and charge of the membrane surface, their main drawback is a limited stability of the modified layer with time, because of possible desorption of the coated/adsorbed polymers than the modification process can be repeated.

Nonfluorinated Membranes: Fuel Cell Applications

Monica Pica
University of Perugia, Department of
Pharmaceutical Sciences, Perugia, Italy

Non-fluorinated membranes for fuel cell applications are a class of ionomeric membranes in which the ionogenic groups, responsible for the proton conduction properties, are attached to a fluorine-free polymeric backbone. Since polymers suitable

for fuel cells must be thermally, mechanically, and chemically stable at temperatures $\geq 80^\circ\text{C}$, non-fluorinated polymers are generally made up of polyaromatic or polyheterocyclic units, such as polysulfones, poly(ether sulfone)s, poly(ether ketone)s, poly(phenylquinoxaline), polybenzimidazole, and polyimides (Roziere and Jones 2003). Polyarylenes are high-temperature rigid polymers, with high Tg values, due to the presence of inflexible and bulky aromatic groups; they are cheap and commercially available and their structure allows the introduction of protogenic groups in order to get proton conduction properties (Smitha et al. 2005). Proton-conducting membranes can be obtained from thermostable non-fluorinated polymers through the following approaches (Roziere and Jones 2003):

- (i) Direct sulfonation of the polymer backbone (poly (aryl ether sulfone)s, poly(aryl ether ketone)s, polyphosphazenes, polyimides). Sulfonating agents such as fuming sulfuric acid, chlorosulfonic acid, trimethylsilyl chlorosulfonate, and sulfur trioxide-triethyl phosphate complexes are commonly used. The sulfonation is carried out either in “bulk” sulfuric acid as solvent or in solutions of dichloromethane. The sulfonation degree is controlled by reaction time, temperature, and the polymer/sulfonating agent ratio. The main drawback is the difficulty to control the distribution of the sulfonic groups along the polymer chains and the possibility of cross-linking with formation of sulfone links between polymer chains.
- (ii) Direct synthesis from monomer building blocks. The combination of sulfonated and non-sulfonated monomers allows a better control of the sulfonation degree and the distribution of the ionogenic groups over the polymer chain.
- (iii) Chemical grafting of sulfonated functional groups to the polymer main chain (polysulfones, poly(ether ketone)s, polybenzimidazole) does not require sulfonated monomers and offers an easier route to introduce locally and densely sulfonated structures into the aromatic polymer backbone.

- (iv) Acid-base complexes. An example is polybenzimidazole/phosphoric acid, in which the proton conductivity is mainly affected by the acid doping level and temperature. Limitations of these systems are the leaching out of the free acid in the presence of liquid water and the poor mechanical properties at high acid doping levels.

Membranes based on sulfonated polymers are commonly prepared by casting polymer solutions, in polar aprotic solvents (NMP, DMF, DMAc, DMSO), on a flat substrate, followed by solvent evaporation and acidification treatment. In all types of sulfonic polyelectrolyte membranes, the acid groups tend to cluster into hydrophilic regions that are hydrated or solvated in the presence of water or water/methanol solutions and are responsible for the water and proton transport; the polymer backbone segregates into hydrophobic regions which provide morphological stability and prevent dissolution in water (Roziere and Jones 2003). The water uptake of sulfonated membranes increases with the water activity, temperature, and number of acid functionalities and affects proton conductivity and mechanical stability. In polyaromatic ionomers with randomly distributed sulfonic groups, the rigid polyaromatic backbone prevents the formation of well-connected hydrophilic channels, and these sulfonated polymers attain suitable conductivities at high ion-exchange capacities (meq of $-\text{SO}_3\text{H}$ groups per 1 g of dry membrane) and high water contents, which negatively affect their mechanical and water resistance (Wang et al. 2012). Polyaromatic block copolymers, with hydrophilic sulfonated polymer segments (forming an interconnected three-dimensional network) and hydrophobic non-sulfonated segments (having a reinforcing effect), should better prevent excessive swelling in water, enhancing mechanical properties and assuring a good proton conductivity (Higashihara et al. 2009; Kim et al. 2004). Polyaromatic ionomers exhibit a methanol permeability lower than that of perfluorosulfonic acid membranes, so that they result particularly suitable for applications in direct methanol fuel cells (Xue and Yin 2006).

Nonlinear Programming

Radoslav Paulen

Department of Biochemical and Chemical Engineering, Technische Universität Dortmund, Dortmund, Germany

Problems of nonlinear programming (NLP) arise in many engineering applications. These involve (complex) process simulations, optimal experiment design for estimation of parameters, parameter estimation, optimal process design, optimal process control, and so on. In general, constrained NLP problems can be mathematically stated as (Bertsekas 1999)

$$\min_x f(x) \quad (1a)$$

$$\text{s.t. } \mathbf{g}(\mathbf{x}) \leq 0 \quad (1b)$$

$$\mathbf{h}(\mathbf{x}) = 0 \quad (1c)$$

where $\mathbf{x}$ represents vector of optimization (decision) variables, $f(\mathbf{x})$ is optimization criterion, and $\mathbf{g}(\mathbf{x})$ and $\mathbf{h}(\mathbf{x})$ stand for sets of inequality and equality constraints, respectively.

If the instance of problem (1a) does not involve (1b) and (1c), then the problem is referred to as unconstrained. Minimizer x^* must satisfy the following property (Boyd and Vandenberghe 2004)

$$\nabla f(x^*) = 0$$

and thus the problem boils down to solving the set of nonlinear equations. For solving this type of problems, one may use well-established algorithms such as steepest descent method and Newton or quasi-Newton methods.

However, in practice, any optimization problem involves constraints naturally. To treat constrained NLPs analytically, one may exploit Karush-Kuhn-Tucker (KKT) conditions which are based on the theory of Lagrange multipliers (Bazaraa et al. 1993). For practical purposes, one usually relies on using numerical methods. These are based on approximation of original problems into an unconstrained form (penalty, barrier, and interior point methods) or generating sequences of simpler but closely related subproblems (SQP and active set methods).

Nonlinear Regression: Levenberg-Marquardt Method

Z. V. P. Murthy
 Department of Chemical Engineering,
 S.V. National Institute of Technology, Surat,
 Gujarat, India

Nonlinear regression (Levenberg-Marquardt method). In almost every discipline of science and engineering, people encounter problem of parameters estimation of nonlinear models.

Among different available methods, Levenberg-Marquardt is a popular method to solve nonlinear least-squares problems effectively due to its ability to converge from a wide range of initial guess values of parameters (Davis 1993). An objective of nonlinear least-squares problem is to minimize the difference between a set of experimental data and the data generated by a model function. Given a set of experimentally observed data (x_i, y_i) , optimize the parameter θ of model function $f(x_i, \theta)$ to minimize the sum of the squares of the deviations. The objective function of least-squares problem is then formulated as

$$F(\theta) = \frac{1}{2} \sum_{i=1}^n r_i^2(x) \quad (1)$$

where n is the number of data points considered, $r_i(x) = f(x_i, \theta) - y_i$ is called a residual, and y_i is y component of the data point at x_i . If the function is a nonlinear in the model parameters vector $\theta = [\theta_1, \theta_2, \dots, \theta_m]^T$, where m is the number of parameters, then minimization of the objective function is carried out iteratively. The Levenberg-Marquardt algorithm starts with an initial guess for the parameters vector θ . In each iteration step, perturbation $\delta\theta$ of parameters is calculated and next iteration proceeds with a new estimate, $\theta + \delta\theta$. Levenberg (1944) proposed algorithm with the following search scheme to update the parameter:

$$(J_K^T J_K + \lambda I) \delta\theta_k = -J_K^T r_k \quad (2)$$

where I is the identity matrix, $\delta\theta$ is the perturbation to the estimated parameters, J is Jacobian matrix of residuals, and λ is a damping factor. Marquardt (Marquardt 1963) suggested update relationship by replacing the identity matrix I , with the diagonal of $J^T J$ resulting into Levenberg-Marquardt algorithm:

$$(J_K^T J_K + \lambda \text{diag}(J_K^T J_K)) \delta\theta_k = -J_K^T r_k \quad (3a)$$

$$\theta^{k+1} = \theta^k + \delta\theta^k \quad (3b)$$

Levenberg-Marquardt method is considered to be a blend of steepest descent and Gauss-Newton

Nonlinear Regression: Levenberg-Marquardt Method, Fig. 1 Plot of true rejection (R) vs. permeate flux (J_v) and its comparison with the values calculated using irreversible thermodynamics model for the CdCl_2 – NiCl_2 –water system at different feed concentrations and feed flow rate of 10 L/min (Reproduced with permission from Elsevier)

Nonlinear Regression: Levenberg-Marquardt Method, Fig. 2 Comparison between experimental and estimated rejection rates of Cr^{3+} , Ni^{2+} , Zn^{2+} , Cu^{2+} , and Cd^{2+} in leachate – A and B as a function of permeate volume flux by using ion transport model (feed flow rate = 5 L/min) (Reproduced with permission from Elsevier)

methods. It takes on a search direction like the steepest descent when the solution is far from a minimum. However, as solution gets closer to optimum, it behaves like that of Newton's method (Marquardt 1963; Le et al. 2012). The main steps involved in Levenberg-Marquardt method are summarized below (Le et al. 2012): (1) starting with an initial guess value of $\theta = \theta^0$ at $k = 0$; (2) specify modest value of $\lambda = \lambda_0$, $\lambda > 0$; (3) at the k th iteration, calculate $F(\theta^k)$; (4) solve equation (3) for θ^{k+1} and evaluate $F(\theta^{k+1})$; (5) if $F(\theta^{k+1})$

$> F(\theta^k)$, increase λ by a factor 10 and go to the step (4); (6) if $F(\theta^{k+1}) < F(\theta^k)$, decrease λ by a factor 10 and go to step (4); and (7) stop when trial solution met desired convergence criteria.

Levenberg-Marquardt method has been used extensively in the membrane separation processes to find membrane transport parameters and characteristics of the membrane using different membrane transport models. Chaudhari and Murthy (2010a, b), and Murthy and Chaudhari (2009a, b) used Levenberg-Marquardt method to determine

nanofiltration (NF) membrane transport parameters and then used those parameters to predict the performance of the membrane in the rejection of various metal ions from different solutions. Figure 1 (Chaudhari and Murthy 2010a) and Fig. 2 (Chaudhari and Murthy 2010b) show some of the results obtained using the Levenberg-Marquardt method. Some modified versions of Levenberg-Marquardt method were also used in membrane separation processes (Soltanieh and Gill 1981; Murthy and Gupta 1997, 1999).

Nonsolvent Induced Phase Separation Process (NIPS) for Membrane Preparation

Franco Tasselli

Institute on Membrane Technology, National Research Council of Italy, ITM–CNR, Rende, Italy

Synonyms

NIPS

Non-solvent induced phase separation process (NIPS) for membrane preparation.

Phase separation processes, in which a solid phase separates from a polymer solution, are the basis for the preparation of all kind of membranes. A scheme of these processes is reported in Fig. 1.

Among them, the *non-solvent induced phase separation* (NIPS) is the most commonly used thanks to its versatility and to the possibility of preparing a great variety of membranes (Mulder 1996). According to this process, the polymer solution is immersed in a non-solvent bath

Nonsolvent Induced Phase Separation Process (NIPS) for Membrane Preparation, Fig. 1 Scheme of the phase separation processes

Nonsolvent Induced Phase Separation Process (NIPS) for Membrane Preparation,
Fig. 2 Phase diagram of a three-component system

(Reprinted from Baker (2004) with permission from John Wiley & Sons Ltd.)

(coagulation bath), typically water, where the exchange of solvent and non-solvent takes place: the solvent migrates from the polymer solution to the coagulation bath, while the non-solvent follows the reverse path, leading to the formation of the membrane. As raw material, many polymers can be used, provided that they are soluble in a solvent or in a mixture of solvents. Membranes both in *flat* and *tubular* conformation can be realized. In the first case, the polymer solution is cast on a support, typically a nonwoven polyester or a glass plate (Baker 2004), by means of a *casting knife* before dipping into the coagulation bath. The most important parameters affecting the structure of the resulting membrane are the composition of the coagulation bath, the composition of the casting solution, the exposure time, the humidity, and the temperature of the air. Also the thickness of the casting solution, generally adjusted in the range from few tens to some hundreds of microns, plays an important role in determining membrane characteristics.

In the case of the tubular conformation, the polymer solution and the *bore fluid* are co-extruded through a *spinneret* giving rise to a self-supporting structure which, depending on the diameter, is classified as *hollow fiber* (diameter below 0.5 mm) or *capillary* membrane (diameter between 0.5 and 5 mm). In addition to the parameters that affect the structure and the performance of flat membranes, in the case of tubular

conformation, the following must be considered: *viscosity* and extrusion rate of the polymer solution, composition and feeding rate of the bore fluid, *air gap* distance, and dimensions of the spinneret.

Some important aspects concerning NIPS, such as the exchange rate of solvent and non-solvent and the velocity of the phase separation, are related to *kinetics* and strongly influence the morphology of the membrane. However, also *thermodynamics* plays a relevant role in phase separation processes. Interactions among polymer, solvent, and non-solvent can be discussed in terms of *free energy* of mixing (ΔG_m) and are described in the *solubility parameter theory*. The thermodynamic stability of three-component mixture (polymer, solvent, and non-solvent) is graphically described by a *ternary phase diagram* (Fig. 2).

The corners of the triangle represent the pure components and the sides are binary mixtures. Points within the triangle represent ternary mixtures. Three regions can be distinguished separated by *binodal* and *spinodal* boundary: the region on the left of the binodal boundary represents the *one-phase* thermodynamically stable region, in turn subdivided in *solution*, *gel* and *glassy* region; between the binodal and spinodal boundary, a *metastable* region, thermodynamically unstable in which no phase separation occurs; and on the right of the spinodal boundary,

a thermodynamically unstable region where phase separation occurs. The polymer solution spontaneously separates into a polymer-rich phase and a polymer-poor phase whose compositions are given by the intercepts of the *tie line* with the binodal boundary.

The formation of membranes by NIPS can be summarized as follows:

- The polymer solution comes in contact with the non-solvent and the exchange of solvent and non-solvent begins.
- As the polymer solution loses solvent and enriches of non-solvent, the composition enters the two-phase region; polymer precipitation occurs giving rise to the formation of a polymer-rich phase and a polymer-poor phase.
- The exchange of solvent and non-solvent proceeds, the composition of the polymer-rich phase moves toward the polymer/non-solvent side, and the membrane is formed.

NOx Effect on Membrane Properties

Colin A. Scholes

Department of Chemical and Biomolecular Engineering, University of Melbourne, Parkville, VIC, Australia

Combustion of fossil fuels at high temperature in air results in the generation of nitrogen oxides, commonly and collectively referred to as NOx. This mixture is dominated by NO and to a lesser extent NO₂, but can also consist of higher nitrogen oxides, such as N₂O₄, but only rarely includes N₂O. The generation of NOx is the result of partial oxidation of N₂ in combustion, as well as nitrogen associated with the fuel. Dependent on the fuel

type and combustion temperature, NOx can exist in the flue gas on the order of 10–500 ppm. Their emission is heavily regulated and must be reduced to 2–5 ppm before flue gas can be vented to the atmosphere. This has implications in flue gas desulfurization and CO₂ postcombustion capture from flue gas.

The effect of NOx on membranes is a sparsely studied area, with the permeability, selectivity, and effects of NO and NO₂ on polymeric membranes relatively unknown. Information on performance must be extrapolated from known properties, such as kinetic diameter and solubility.

NO has a smaller kinetic diameter than most gases found in flue gas, such as N₂, O₂, and CO₂. Hence, molecular sieve-based membranes will show selectivity for NO relative to these gases. Conversely, NO₂ has a larger kinetic diameter than other gases present in flue gas and will be retained in the retentate. For nonporous membranes where solubility is an important factor, it is expected that membranes show selectivity for NO₂ compared to NO, given the difference in critical temperature.

For CO₂-selective membranes for carbon capture from flue gas, nonporous polymeric membranes will display CO₂/NO selectivity because of strong CO₂ solubility. This has been observed for the glassy polymeric membranes of polysulfone, and the polyimides Matrimid 5218 and 6FDA-TMPDA (Table 1; Scholes et al. 2009). Conversely, NO₂ will have a greater permeability than CO₂ in nonporous membranes because of strong NO₂ solubility, and this has been reported for poly tetrafluoroethylene (PTFE), with a permeability of 15.9 barrer and a NO₂/CO₂ selectivity of 1.6 (Pasternak et al. 1970).

The plasticization and aging effects of NOx on membranes has not been reported in the literature to date. In the presence of water, NOx readily forms nitric acid, and this will degrade membrane

NOx Effect on Membrane Properties, Table 1 NO permeability (barrer) through glassy polymeric membranes

	Polysulfone	Matrimid 5218	6FDA-TMPDA
NO permeability (barrer)	3.1 ± 0.6	3.7 ± 0.6	168 ± 16

materials over time. Hence, in the humid environment of flue gas it is expected that NO_x will have similar degradation performance on membranes as those observed for SO_x.

Nuclear Science and Technology, Membrane in

Grażyna Zakrzewska-Kołodziej
Institute of Nuclear Chemistry and Technology
Instytut Chemii i Techniki Jądrowej, Warszawa,
Poland

Recent achievements in the area of membrane processes are being applied for solving the problems in nuclear science and technology. The most important application of membrane processes is the treatment of liquid radioactive waste, often combined with the recovery of valuable materials such as water, boric acid, metals, or radioactive isotope of hydrogen – tritium. Separation of stable isotopes and enrichment of uranium in the ²³⁵U isotope for production of nuclear fuel, as well as cleaning the exhaust gas from nuclear power plants, are possible with membrane processes. Reverse osmosis may be applied in nuclear desalination; other membrane processes, like membrane distillation, are also considered as an alternative to energy-intensive distillation methods.

Separation of Isotopes

The issue of membrane in isotope separation (► [membrane for the isotope separation](#)) is

discussed in the scientific literature from the first application of molecular diffusion for enrichment of uranium in its less abundant ²³⁵U isotope for military purposes during the Second World War. The method is still applied in several installations producing the enriched uranium for nuclear fuel for power reactors. The studies on separation of isotopes of other elements like hydrogen, oxygen, nitrogen, carbon, lithium, chlorine, and lanthanides, by using different membrane processes are carried out in many laboratories.

Radioactive Waste Treatment

The application of membrane processes for radioactive waste treatment (Membranes in nuclear waste treatment) is a common industrial practice. Nuclear waste processing by pressure-driven membrane processes (nuclear waste processing by pressure-driven membrane processes) is a standard method applied in nuclear power plants and nuclear centers; thermal membrane process (nuclear waste processing by thermal processes), namely, membrane distillation, was proposed for liquid low and intermediate waste concentration. Advanced researches are carried out to employ liquid membranes for processing radioactive waste, especially the waste from the back-end of nuclear fuel cycle. Membrane contactors pose new field of applications including such techniques like supported liquid membranes (nuclear waste processing by supported liquid membranes) and membrane liquid–liquid extraction.

Separation of Tritium

Tritium is emitted by nuclear reactors and fuel reprocessing plants in gaseous and liquid (HTO) forms. The studies on application of polymeric membranes for both gaseous tritium and tritiated water separations are carried out in many laboratories. For separation of HTO, the membranes from poly[bis(phenoxy)phosphazene] and carboxylated derivatives were used (Duncan and Nelson 1999). Membranes made from regenerated cellulose, polysulfone, and

polytetrafluoroethylene were also tested for this purpose. Separation factors $\alpha_{\text{H}_2\text{O}/\text{HTO}}$ in membrane process were not higher than 1.04 for cellulose and 1.02 for polysulfone, while for PTFE membranes were as high as 1.06–1.22 (Zakrzewska-Trznadel 2006).

Recently published papers cover the application of polymeric gas separation (GS) membranes for recovery of tritium compounds (HT, HTO) (Le Digabel et al. 2003; Iwai et al. 1999; Ishida et al. 2000). Such membranes like those manufactured from glassy and amorphous polymers, mainly polyimide and polycarbonate, as well as polyphenylene oxide, assembled in modules (e.g., Mc Generon Inc., type B210, Ube Industries, Ltd. Type NM-B05A, Parker, type 2112-NX-1-300) were considered.

The works performed on hydrogen isotope separation by permeation methods concern nuclear reactor safety and thus release of tritium from nuclear water reactors and fuel reprocessing plants. On the other hand, a lot of space is devoted to researches on the security of the fuel cycle for future fusion reactors (Basile et al. 1995). Various systems are proposed: palladium alloy-based separators, catalytic systems with metallic membranes, integrated systems with ceramic catalytic reactors, and electrolytic reactors.

Separation of Radioactive Gases

Apart from separation of tritium from radioactive gaseous waste produced by nuclear reactors, the other pollutants like noble gases may be separated by membrane methods. In recent years, the works showing the interest in membrane separation processes of noble gases (Nörenberg et al. 2001) were published. Membranes used for this purpose were polyimide hollow fibers and flat-sheet filters made from polyethylene terephthalate (PET) or oriented polypropylene. The methods for selective separation of tritium from the gases released from nuclear facilities have been studied primarily in the context of measuring the emission of this isotope (Sasaki et al. 2003).

Membrane Methods for Nuclear Desalination

Because seawater desalination is energy intensive, the use of energy from nuclear reactors for desalination systems seems to be justified. In some cases membrane processes can be competitive with thermal methods like multistage flash evaporation, multiple effect distillation, or vapor compression. There are several examples of application of RO in such nuclear reactor-desalting systems (IAEA Technical Reports Series 2000; Kim et al. 2002). The employment of membrane distillation to produce desalted water with nuclear energy was also considered (Khayet et al. 2006).

Nuclear Waste Processing: Pressure-Driven Membrane Processes

Grażyna Zakrzewska-Kołodziej
Institute of Nuclear Chemistry and Technology
Instytut Chemii i Techniki Jądrowej, Warszawa,
Poland

The pressure-driven membrane processes such as reverse osmosis (RO), nanofiltration

(NF), ultrafiltration (UF), and microfiltration (MF) are the most commonly used membrane methods of radioactive waste processing. The reasons for a wide use of membrane methods are numerous: they are mature technologies with long design and operation experience, well proven in nuclear industry, with broad spectrum of membranes and membrane modules developed. The variety of pressure-driven membrane processes covers wide spectrum of media: from ionic species to large particles (Fig. 1). Therefore, they are suitable for large number of applications, being flexible in process configurations and system optimization. They can be easily integrated with other conventional methods to form efficient treatment systems. Pressure-driven membrane processes are especially convenient for the concentration of large volumes of low and intermediate level radioactive waste with low salinity and low radioactive species content.

Reverse osmosis, well-developed technology, has found many applications in nuclear industry. It is used for removal of radionuclides from various streams in nuclear power plants: reactor coolant, floor drains, reactor outage waste, spent resin

Nuclear Waste Processing: Pressure-Driven Membrane Processes, Fig. 1 Pressure-driven membrane processes – range of application

Nuclear Waste Processing: Pressure-Driven Membrane Processes, Fig. 2 Three-stage RO plant for the treatment of institutional radioactive waste at Radioactive Waste Management Plant at Swierk, Poland

sluice water, the waste from steam generator chemical cleaning, and fuel cooling pond water. It can be applied for the liquid waste from research activities and medical applications (Fig. 2), as well as for cleaning the defense and reprocessing effluents (IAEA Technical Reports Series 2004). Since RO rejects all dissolved matters from water solution, the product from RO modules – high-purity water – may be recycled within the nuclear power plant. Big variety of RO systems is available in the market and various polymeric materials are used for membrane manufacturing.

Nanofiltration is able to separate monovalent ions from multivalent ions or organic compounds from monovalent ions. The best known application of NF is boric acid recovery from reactor cooling water (Zakrzewska-Trznadel 2008). NF can be applied for removal of dissolved uranium ions from wash solutions discharged from fuel fabrication plants. Integrated with macromolecular ligands, NF was applied for separation of lanthanides and actinides (Chitry et al. 2001a) and separation of neodymium and gadolinium isotopes (Chitry et al. 2001b).

Ultrafiltration is a good pretreatment method before reverse osmosis. It is used for removal of colloid matters and particles to avoid the fouling of RO membranes, as well as alpha-emitting substances, namely, actinides, which are often in colloidal form. Combined with chelating compounds or dispersed sorbents that bind small ions, UF can be applied for removal of dissolved radioactive metal ions from diluted aqueous solutions. UF membranes reject complexed or sorbed ions

allowing uncomplexed ions to pass through as permeate. Ultrafiltration may be employed for the treatment of water from fuel storage ponds, cleaning the laundry wastes, solvent wash liquors, and plutonium evaporator overheads from reprocessing lines or purification of effluents from fuel fabrication plants. The decontamination factors reported in the literature are in the range of 1000 for α emitters and 100 for β and γ species, and the overall volume reduction of the order of 10^4 is achieved with UF systems. Inorganic, ceramic membranes in the region of UF pore size are offered in the market, which enhance the potential of the process.

Microfiltration is applied as a pretreatment stage before RO or UF; it can be also used separately for the concentration of radioactive suspensions and dewatering of concentrated sludge. It may be applied with conjunction of precipitation process to remove various kinds of radionuclides. Both polymeric and inorganic membranes are employed for MF process.

In spite of intensive studies in the field of membrane technologies and continuous development of novel processes, the pressure-driven membrane processes remain the leading membrane methods in nuclear industry Zakrzewska-Kołtuniewicz (2015).

Nuclear Waste Processing: Supported Liquid Membranes

Grażyna Zakrzewska-Kołodziej
Institute of Nuclear Chemistry and Technology
Instytut Chemii i Techniki Jądrowej, Warszawa,
Poland

Supported liquid membranes (SLM), also called immobilized liquid membranes, have found a number of applications in nuclear industry – from uranium mining to reprocessing of spent nuclear fuel. In supported liquid membrane, two phases, feed and receiving solutions, are separated by porous barrier with organic phase inside the pores. In order to increase the mass transport rate between the phases, the carrier, which forms complex with one of the separated

species, is introduced to the organic phase. Such a facilitated transport causes not only fast transport rates but also results in higher selectivity of the process.

SLM were studied for radioactive waste treatment and for removal of actinides and fission products from the waste after reprocessing of nuclear fuel. Radionuclides, such as cesium, strontium, cerium, and europium, were separated from radioactive solutions to reduce the radiotoxicity of the waste. Uranium plutonium and americium removal from the wastes produced in the back-end of fuel cycle, as well as the effective methods for actinides partitioning, were broadly described in the literature. Example applications are collected in the Table 1.

The main drawback of immobilized liquid membranes is their low stability associated with loss of extractant via volatilization or dissolution into contacting phase (Kołodziej and Drioli 2008). The advantages are high selectivity of the method allowing a wide range of applications and easy optimization of the membrane-extractant system. Although the industrial application of this process is far from implementation, ongoing research on new extracting agents for actinides takes place in many laboratories around the world. A solution to the problem of loss of extracting agent may be development of inclusion membranes. Polymer inclusion membranes (PIM) in some cases incorporate base polymer and a suitable extractant, while in other cases a plasticizer may be needed to be added (Bayou et al. 2010). PIM have been successfully developed for extraction of radionuclides from radioactive waste using various extracting agents like TOPO, Cyanex 272, Cyanex 301, Cyanex 302, CMPO, TODGA, D2EHPA, and crown ethers (Kusumocahyo et al. 2004; Kozłowski et al. 2006; Bhattacharyya et al. 2011). Another approach for the extraction of radionuclides with selective organic reagents is application of membrane solvent extraction carried out in membrane contactors (Drioli et al. 2005).

Nuclear Waste Processing: Supported Liquid Membranes, Table 1 Supported liquid membranes for treatment of radioactive waste

Separated radionuclides	Application	Extracting agent (LM)	Stripping solution	Support	Reference
Pu(IV)	Separation of plutonium from radioactive waste	Tri-n-butyl phosphate (TBP)	0.1 M $\text{NH}_2\text{OH}\cdot\text{HCl}$ in 3 M HNO_3	Hollow fiber polypropylene (Enka) membrane	Rathore et al. 2001
Pu(IV)	Separation of plutonium from radioactive waste	2-ethylhexyl 2-ethylhexyl phosphonic acid in n-dodecane	0.05 M HNO_3 and 0.3 oxalic acid solution	Polypropylene Enka 2E HF-PP membrane	Kedari et al. 1999
U(VI) ^{233}U ,	Recovery of uranium from 6 M HCl at the back-end of fuel cycle	Alamine 336 in toluene	Distilled water	PTFE flat sheet membrane	Lakshmi et al. 2004
^{232}Th	U/Th separation in 4 M HNO_3 in the presence of ^{137}Cs , $^{85,89}\text{Sr}$, and ^{59}Fe	N,N-di(2-ethylhexyl) isobutyramide (D2EHIBA) in n-dodecane	0.01 M HNO_3	PTFE flat sheet membranes, 0.45 μm , 72 % porosity (Sartorius)	Shailesh et al. 2006
U(VI)	Actinides partitioning	N,N,N',N'-tetra-2-ethylhexyl-3-pentane-diamide (T2EHDGA) in n-dodecane, 30 % iso-decanol as the modifier	0.01 M HNO_3	PTFE flat sheet membranes, 0.45 μm , 64 % porosity	Panja et al. 2011
U(VI)	Recovery of actinides at the back-end of fuel cycle from acidic feeds	Tetraoctyldiglycolamide (TODGA) in n-dodecane	0.1 M HNO_3	PTFE flat sheet membranes	Panja et al. 2009
U(VI)	Recovery of actinides at the back-end of fuel cycle from acidic feeds	N,N,N',N'-tetra-2-ethylhexyl-3-pentane-diamide (T2EHDGA) in n-dodecane, 30 % iso-decanol as the modifier	0.01 M HNO_3	PTFE flat sheet membranes	Panja et al. 2012
U(VI)	Extracting of uranyl ions from 6 M HCl environment	Aliquat 336 (N-methyl-N,N-diocetyl octan-1-ammonium chloride)	Distilled water	PTFE flat sheet membranes (Sartorius)	Mohapatra et al. 2006
U(VI)	Recovery of uranium from nitrate media	TBP in kerosene	NaOH	Hollow fiber membrane contactor	Ramkul et al. 2007
U(VI)	Separation of uranium from phosphoric acid	Tri-n-octylphosphine oxide (TOPO) in n-dodecane	Ammonium carbonate	PTFE flat sheet membranes, 0.45 μm , 84 % porosity	Singh et al. 2007
Am(III)	Extraction Am (III) from 1–6 M HNO_3	TEHDGA in dodecane	0.1 M HNO_3	PTFE flat sheet membranes (Sartorius) 0.20–5 μm	Panja et al. 2008

Nuclear Waste Processing: Thermal Processes

Grażyna Zakrzewska-Kołodziej
Institute of Nuclear Chemistry and Technology
Instytut Chemii i Techniki Jądrowej, Warszawa,
Poland

Despite many potential benefits posed by membrane distillation (MD), the scale of applications

Nuclear Waste Processing: Thermal Processes, Fig. 1 Pilot plant for liquid radioactive waste concentration at Institute of Nuclear Chemistry and Technology, Warsaw

of this process is still limited. Temperature gradient-driven membrane processes were developed for concentrating liquid radioactive waste from institutional applications (Chmielewski et al. 2000; Fig. 1).

As the MD process is characterized by high retention of nonvolatile solutes, large decontamination factors are expected for radionuclides, which are present in liquid radioactive effluents in mainly ionic form. The process was tested in laboratory scale and in the pilot plant. High decontamination was achieved for radionuclides, such as ^{192}Ir , ^{170}Tm , ^{140}La , ^{134}Cs , ^{133}Ba , $^{192\text{m}}\text{In}$, $^{110\text{m}}\text{Ag}$, and ^{65}Zn , which were completely retained by the membrane, as well as for ^{137}Cs and ^{60}Co , which were predominant components of institutional radioactive waste. The decontamination factors for these radionuclides were 44 and 4,336, respectively (Zakrzewska-Trznadel et al. 1999). In the closed-loop membrane

Nuclear Waste Processing: Thermal Processes, Fig. 2 Specific conductivity of retentate and distillate vs. time during the concentration of radioactive waste

Nuclear Waste Processing: Thermal Processes, Fig. 3 Specific radioactivity of retentate and distillate vs. time during the concentration of radioactive waste

apparatus, the specific conductivity of the retentate does not change, while specific conductivity of distillate decreases (Fig. 2). In the same time, radioactivity of the retentate is also stable (however, small sorption in the unit is observed), and the radioactivity of distillate is on the natural background level (Fig. 3). The distillate produced by MD module is clean water, which can be reused in the nuclear plant.

The novel process of MD is advantageous, not only because of high decontamination factors and retention factors but also due to the simplicity of the apparatus applied and its ability to utilize waste heat from power sources such as nuclear reactors. The other advantages of MD are a possibility of running the process to high-solute concentrations, sufficient for direct immobilization of the waste, a high concentration in one-stage operations, elimination of high pressures, and reduction of sorption of radioactive species inside the

membrane pores since pores are filled with water vapor. MD can be easily integrated with other processes to form hybrid systems (Zakrzewska-Trznadel 2008). Membranes manufactured from PTFE, PP, or PVDF are used in the process. The average pore size of the membrane is 0.2–1.0 μm and the volume porosity is 70–80 %.

Different configurations were tested: shell-and-tube capillary, spiral-wound modules, and plate-and-frame systems with flat sheet membranes (Khayet et al. 2005). All arrangements of MD are possible to use: direct contact, air gap, sweep gas, and vacuum membrane distillation; however, the most convenient configuration for industrial applications, as well as this selected for radioactive waste processing, seems to be the direct contact MD.

Beneficial solution appears application of membrane distillation in nuclear desalination, both for radioactive waste treatment and to produce desalted

water (Khayet et al. 2006). Thermally driven process was also proposed for separation of light isotopes of hydrogen and oxygen for production of heavy water used in CANDU type reactors, and heavy-oxygen water for applications in nuclear medicine, i.e. PET examinations (Zakrzewska-Trznadel et al. 1996; Chmielewski et al. 2002).

heterogeneous, surface-catalyzed nucleation (Cahn 1960). The nucleation stage can be surpassed when a seed material is used, on which crystallization can take place by addition of new atoms, ions, or polymers. This is typically applied in reactors for precipitation such as the pellet reactor for water softening. This is heterogeneous precipitation, for which a moderately supersaturated solution is needed (with stability index $SI = 1-2$). Heterogeneous precipitation is easier than homogeneous precipitation, since there is no need to create a new surface (and to supply the energy needed for this). This also allows a better control of the crystallization.

Homogeneous nucleation sets off with the creation of a small nucleus, which contains the newly forming crystal. This stage in the process is relatively slow, because the initial crystal components have to arrange in the correct orientation and position to adhere and form the crystal. Therefore, a larger oversaturation is needed ($SI = 3-4$). Once a nucleus is formed, crystals may grow more rapidly because they contain dislocations and other defects, which act as growth points and catalysts for structural transformation and long-range order formation (Frank 1949).

Nucleation stage crystal growth can be described by the self-consistent theory of nucleation (Girshick and Chiu 1990). According to the self-consistent theory, the Gibbs free energy ΔG needed for nucleation can be written as:

$$\Delta G = (4\pi r^2 - s)\sigma - (n - 1)k_B T \ln S$$

in which k_B is the Boltzmann constant, S is the supersaturation, and s is the surface area of a monomer. From this, the nucleation rate can be calculated as:

$$I_{SCT} = \frac{\exp\left(\frac{\sigma s}{k_B T}\right)}{S} I$$

in which I is the rate calculated from the classical nucleation theory. The exponential coefficient in the equation takes the surface energy of the monomer into account.

Nucleation Stage Crystal Growth

Bart Van der Bruggen

Department of Chemical Engineering, Process Engineering for Sustainable Systems (ProcESS), KU Leuven, Leuven, Belgium

Nucleation is the initial stage of crystal growth and can be either homogeneous nucleation or

Nucleation is an important phenomenon in membrane synthesis, mainly applied for synthesis of inorganic membranes. For example, Lin et al. (2001) prepared silicalite membranes by a single hydrothermal synthesis on nanoscale-silicalite-seeded porous tubular supports. An incompact crystal layer was obtained, especially on the unseeded support. Silicalite crystals preferentially grew onto the support tubes seeded with silicalite powders with size below 4 μm . The silicalite seed particles mainly provided nucleation sites (heterogeneous nucleation) and enhanced silicalite crystal growth in all directions onto the support, resulting in the formation of a thin and dense crystal layer.

For polymeric membranes, the nucleation stage is typically fast, and homogeneous nucleation is usually applied.

A direct application of nucleation for crystallization is encountered in membrane crystallization (Curcio et al. 2001). In a membrane crystallizer, a solution is concentrated by, e.g., membrane distillation, so that a supersaturated solution is obtained (Curcio and Drioli 2005). Subsequently, the supersaturated solution is crystallized in a second unit, which yields crystals with extraordinary purity. The process uses heterogeneous nucleation due to the presence of a membrane surface acting as growth points. Thus, the membrane is used as an active surface to promote heterogeneous nucleation, but also for mass transfer. This allows a good process control and fast crystallization; membrane-assisted crystallization is in that sense superior to other crystallization methods. For these reasons, membrane crystallization is a promising process not only for inorganic salts (Van der Bruggen et al. 2004) but also for proteins with substantial added value (Di Profio et al. 2003). A high uniformity in size was

obtained for crystallization of trypsins in a membrane crystallizer (Di Profio et al. 2005), with crystals produced in forced solution flow found to be more uniform than those obtained in a quiescent membrane system. The crystallization system was further optimized by increasing solution velocity to a maximum.

O₂/N₂ Separation

Ahmad Fauzi Ismail

Faculty of Chemical and Energy Engineering,
Universiti Teknologi Malaysia, Advanced
Membrane Technology Research Centre
(AMTEC), Johor Bahru, Johor, Malaysia

Separation of air into oxygen and nitrogen is an important process, and this separation process has been applied in an industrial scale such as oxygen (O₂) enrichment from air (medical devices) and nitrogen (N₂) enrichment from air (used as protecting atmosphere for oxygen-sensitive compounds) (Jeazet et al. 2012). There are three technologies that currently exist for separating oxygen and nitrogen from the air including cryogenic distillation, pressure swing adsorption (PSA), and membranes. Among these three technologies, cryogenic distillation is considered the most mature technology and allows for the production of both high purities (>99 %) and large-scale productions. However, this technology is renowned to be complex, expensive, and energy intensive, which consumes about 15 % of the electrical output of the power station (Hashim et al. 2011).

PSA is a technology that used to separate some gas species from a mixture of gases under pressure based on the molecular characteristics of the species and affinity for an adsorbent material. Under high pressure, gases tend to be attracted to solid

surfaces (adsorbed), and different gases tend to be attracted to different solid surfaces. For example, in air mixture, carbon molecular sieves (CMS) as the adsorbent bed will adsorb oxygen and water vapor molecules under high pressure while allowing N₂ gas to pass through. Rufford et al. (2012) claimed that the preferential adsorption of components from a gas mixture can be achieved by one, or a combination, of the following mechanisms:

1. Differences in the adsorbate-surface interactions and/or adsorbate packing interactions when the system reaches equilibrium
2. Differences in the size and/or shape of gas molecules
3. Differences in the diffusion rates of molecules through the adsorbent pores

Yet, the main disadvantage of PSA occurs when large flow rates of N₂ are needed; therefore, a large vessel needs to be utilized which consequently increased the installation cost.

The development of membranes for partial air separation progressed rapidly since the 1980s, and this technology is attractive compared to the conventional separation facilities because membrane-based devices are much smaller and can be operated at lower temperature. For dense polymeric membrane, the differences in solubility and diffusivity of O₂ and N₂ in and through the membrane materials will make the separation between the gases occurred. In solution-diffusion model,

permeants dissolve in the membrane material and then diffuse through the membrane down a concentration gradient. Polyimide, polycarbonate, polysulfone, polyethersulfone, and other aromatic polymers are commonly used as polymeric membrane-based devices for gas separation. Mixed matrix membrane (MMM) is a combination of polymer matrix with molecular sieve materials. Separation of gases through molecular sieving materials depends on the differences in molecular size of the gases. By combining the polymer matrix and molecular sieve materials, MMM with enhanced performance, heat, and chemical resistance can be developed.

Other types of membranes that foreseen as the promising technology to replace cryogenic separation for high purity and bulky supply of O₂ from air separation are ion transfer membranes. Ion transfer membranes are solid inorganic oxide ceramic materials with complex crystalline structures. These dense membranes allow oxygen ions to diffuse in the direction of decreasing O₂ partial pressure given an adequate electronic conductivity that allows the counter migration of electrons (Steeneveldt et al. 2006). The movement of O₂ ions down the membrane is charge compensated by the opposite movement of electrons. Then, the oxygen ions release their electrons and recombine to form molecular oxygen at the low partial pressure end. Therefore, the separation of oxygen via ion transfer membrane concept is achieved with the ability of the oxide membrane to conduct both ions and electrons (Leo et al. 2009). Oxygen-enriched air at various concentrations can be achieved in polymeric membrane, whereas ion transfer membranes can give purities of close to 100 %. However, until now both membranes have not been built for large-scale gas separations (Burdyny and Struchtrup 2010).

Off-Gas from Catalytic Reforming

A. Baudot

Physics and Analysis Division, IFP Energies
Nouvelles, Solaize, France

The largest source of hydrogen in the refinery is the off-gas of the catalytic reforming unit. Catalytic reforming is a reaction using precious metal (platinum or rhenium)-based catalysts that converts alkane-containing naphta into two main products: aromatics and hydrogen. The produced hydrogen generally contains from 10 % to 30 % of cracked hydrocarbons ranging from C1 to C6+ as well as traces (at the ppmv level) of HCl and aromatics (Yampulski and Freeman 2010).

As a general rule the hydrogen produced in the catalytic reforming is purified via a PSA (pressure-swing adsorption) unit prior to being reintroduced in other hydrogen-consuming units of the refinery such as hydrotreatments or hydrocracking units. PSA proves to be a very profitable unit for such an application, as this technology allows to reach very high purities in hydrogen (>99 % molar) and high yield as the tail gas

flow of the adsorber, mainly composed of the hydrocarbon part of the reformer off-gas, is very small compared to the feed gas flow. Membrane-based gas permeation unit is sometimes used to purify the hydrogen contained in the off-gas of the catalytic reformer; especially it is necessary to regenerate the catalyst. In this case, when small hydrogen feed flows (up to $1000 \text{ Nm}^3 \cdot \text{h}^{-1}$) and medium hydrogen purities (between 90 % and 98 % molar) are required, gas permeation proves economically viable at the industrial scale.

Nowadays, three main membrane providers offer hydrogen purification permeators:

- *Air Products* with the *Prism*[®] silicon-coated polysulfone membranes (issued from *Monsanto*). *Air Products* claims that the life-time of the *Prism*[®] modules can be more than 15 years.
- *Ube Industries* with polyimide hollow fiber membranes.
- *Air Liquide* with the *MEDAL* polyimide and high-selectivity polyaramide membranes.

All those membranes are based on glassy polymers and offer a diffusion-based hydrogen selectivity. Today's membranes have high H_2/CH_4 selectivities (from 35 to 200 at 80 °C (Roman et al. 1991)). For instance, *Air Products* claims that a single-stage array of *Prism*[®] modules is able to raise the concentration of gases from 10 % to 30 % up to 70–90 % ([Air Products website](#)), while *Medal* membranes are able to raise the concentration of a gas at 51 bar from 86 % in hydrogen up to 98 % with a permeate pressure at 30 bar and a residue containing 52 % of hydrogen at 50 bar ([Medal Internet website](#)).

Hydroxyl radical (•OH) is known to be a very powerful oxidizing agent for efficiently removing persistent organic pollutants (POPs) from water. It is the second strongest oxidizing agent after fluorine with a standard reduction potential of $E^\circ(\text{•OH}/\text{H}_2\text{O}) = 2.8 \text{ V/SHE}$.

Some common techniques for generation of hydroxyl radical (•OH) can be listed as follows: (i) the chemical oxidation processes in homogeneous phase ($\text{H}_2\text{O}_2/\text{Fe}^{2+}$ and $\text{H}_2\text{O}_2/\text{O}_3$), (ii) the photocatalytic processes in homogeneous or heterogeneous phase ($\text{H}_2\text{O}_2/\text{UV}$, O_3/UV , TiO_2/UV and $\text{Fe}^{2+}/\text{H}_2\text{O}_2/\text{UV}$), (iii) the sonochemical processes, and (iv) the electrochemical processes (Zhou and Smith 2002).

The basic chemical oxidation process is based on the Fenton reaction, in which •OH is formed at the optimum pH of 2.8–3.0 by reaction between iron catalyst and hydrogen peroxide:

When UV_A light is applied for the photoelectro-Fenton method (PEF), there is a production of additional •OH from photoreduction reaction: $[\text{Fe}(\text{OH})]^{2+} + h\nu \rightarrow \text{Fe}^{2+} + \text{•OH}$. A similar behavior is observed when sunlight is used as a photon energy source in the solar photoelectro-Fenton method (SPEF).

In the sonoelectro-Fenton (SEF) process, the additional generation of •OH is produced by water decomposition from sonolysis.

In the case of AO (anodic oxidation) and $\text{AO}/\text{H}_2\text{O}_2$, heterogeneous •OH is generated at the anode surface from water oxidation under the

application of a high current density. This process can be much more efficient when BDD (boron-doped diamond) is used as an anode instead of Pt (Brillas et al. 2009).

Through photolysis of hydrogen peroxide, hydroxyl radicals are generated by irradiating H_2O_2 under laser light at wavelength of 405 nm, and the amount of hydroxyl radical produced increases with the irradiation time (Ikai et al. 2010).

In addition, the ozonation process is also another interesting way of producing $\cdot\text{OH}$. Ozone at elevated pH (>8.5) will be decomposed into hydroxyl radicals. In the $\text{O}_3/\text{H}_2\text{O}_2$ process, often called the peroxone process, although H_2O_2 reacts very slowly with the ozone molecule in water, its conjugated base (HO^-) can rapidly react with molecular ozone to form hydroxyl radicals: $\text{HO}_2^- + \text{O}_3 \rightarrow \cdot\text{OH} + \text{O}_2^- + \text{O}_2$.

In the O_3/UV process, the reaction mechanism starts with the activation of the ozone molecule by UV irradiation to form oxygen radicals, which then recombine with water to form $\cdot\text{OH}$ radicals.

Heterogeneous photocatalytic processes such as TiO_2/UV and $\text{TiO}_2/\text{H}_2\text{O}_2/\text{UV}$ can readily generate hydroxyl radicals on the surface of particles when absorbing UV light: $\text{h}^+ + \text{H}_2\text{O} \rightarrow \cdot\text{OH} + \text{H}^+$ (Zhou and Smith 2002).

As presented, technologies of hydroxyl radical ($\cdot\text{OH}$) production are diversified and are still in progress thanks to the development of new catalytic and photocatalytic nanomaterials.

Oil-Water Emulsion

Na Li

Department of Chemical Engineering, School of Chemical Engineering and Technology, Xi'an Jiaotong University, Xi'an city, China

Oil-water emulsion is a dispersion of one liquid in another one with which it is immiscible or poorly miscible. Liquids are normally an organic phase (an "oil") and an aqueous solution (a "water"), respectively. The dispersed liquid is present in the form of droplets in the continuous phase. Direct emulsions are composed of droplets of an organic liquid dispersed in an aqueous solution (O/W), while inverse emulsions are composed of aqueous droplets dispersed in an organic liquid (W/O). Emulsions play an important role in the formulation of various products such as foods; examples of O/W emulsions are dressings, artificial milks, cream liqueurs, etc., and examples of W/O emulsions are margarines and low-fat spreads. In addition, there are numerous nonfood emulsions like ore and petroleum recovery, cleaning and polishing, pharmaceutical products, cosmetics, pesticides for crop protection, bitumen (for road application), water-based paints, photographic films, paper coatings, textiles, leather, etc (Nazir et al. 2010).

Emulsions are thermodynamically unstable systems, that is to say, their free energy of formation is greater than zero, and as such will show a tendency to break (Capek 2004). Instability of emulsion occurs by creaming and coalescence. Creaming is exhibited if the two phases differ in specific gravity and if the emulsion particles are so large initially, or grow to such a size, that they are not responsive to Brownian movement. Coalescence of emulsion particles is often irreversible and is a case of true instability. Coalescence occurs when the interfacial film ruptures at the point of juncture of two particles of the discontinuous or internal phase. It may be reversible if a relatively large proportion of emulsifier is

employed and if the emulsifier has been chosen so as to afford the greatest ease of emulsification (Grayson et al. 1979). A most successful method used to choose proper emulsifying agents for a given system is HLB method. The HLB stands for hydrophile-lipophile balance. HLB number is assigned to each surface-active agent. Those materials with HLB numbers in the range of 4–6 are suitable as emulsifiers for W/O emulsion, while only those with HLB numbers in the range 8–18 are suitable for the preparation of O/W emulsion.

In the evaluation of emulsions, there are a number of fairly standardized measurements. For surface and interfacial tension, the measurements include capillary-height method, drop-weight method, ring method, etc. The viscosity of an emulsion is an important factor in determining its stability as well as from the point of view of ultimate use. Viscosity measurements may also be a guide to the type of emulsion (O/W or W/O). Three basic methods of viscosity measurement are capillary tube methods, falling ball methods, and rotational methods. It is important to determinate the type of emulsion. Unfortunately, an unequivocal determination may not always be possible, and deductive reasoning based on the data obtained from several methods may be required. Desired information may be obtained from five classic methods: dye solubility method, phase dilution method, conductivity method, fluorescence method, and wetting of filter paper. In studies of the stability of emulsions, the change in the particle-size distribution with time is often an important datum. There are, in general, four distinct methods by which this information may be obtained, i.e., by microscopic observation, by various sedimentation techniques, by light-scattering measurements, and by instrumental counting (Becher 1965).

The emulsion is prepared by mechanical disruption of the dispersed phase into the continuous phase. Conventional methods apply shear and extensional stresses to the product. Popular types of equipments are colloid mills, rotor-stator systems, high-pressure homogenizers, and ultrasonic

homogenizers, and these systems show poor control over droplet size and distribution. New methods for emulsification using microstructured systems like membrane emulsification and microchannel emulsification have received much attention. For membrane emulsification, two methods of operation are used: cross-flow membrane emulsification and premix membrane emulsification. In cross-flow membrane emulsification, the emulsion is formed by pushing the to-be-dispersed phase through a membrane into the cross-flowing continuous phase. Ideally, droplet size can be controlled primarily by the choice of the membrane, the cross-flow velocity, and the transmembrane pressure. Contrary to cross-flow emulsification, premix emulsification can be used to produce emulsions with high dispersed phase fraction, albeit that the size of the droplets is not as monodisperse as for cross-flow emulsification (Nazir et al. 2010).

Olefin and Paraffin Separation

A. Baudot
Physics and Analysis Division, IFP Energies
Nouvelles, Solaize, France

Light olefins (alkenes), such as ethylene and propylene, are base chemical intermediates that are used for the production of raw chemicals and

polymers. Those olefins are separated industrially from their paraffin (alkane) counterpart in very energy-consuming distillation operations. Membrane separation could possibly constitute an attractive highly modular and less energy-consuming alternative option for olefin/paraffin separation.

Since more than 20 years, the performances of a very wide array of membrane materials for olefin/paraffin separation have been studied at lab scale mainly by academic teams. We provide here a brief overview of the advantages and limits of each membrane material family. For further reading, extensive and detailed reviews concerning the use of several types of membrane materials for olefin/paraffin separation can be found in various recent papers (Ravanchi et al. 2009; Burns and Koros 2003; Azhin et al. 2008).

Glassy Polymer Membranes

If compared to other glassy polymers offering molecular sieving properties, phenylene polyoxide offers the “best” selectivity/permeability compromise for ethylene/ethane separation (Tanaka et al. 1996; Ilcinich et al. 1992).

Concerning propylene/propane separation, 4,4'-hexafluoroisophtalenediphtalic dianhydride (6-FDA)-based aromatic polyimides favor two conditions that explain why, for comparable selectivity values, such fluorinated polyimides display higher permeabilities toward propylene than the other types of polymers (Hoehn 1974):

- Rigid polymer chains that promote molecular sieving selectivity. This can be achieved if the monomers are connected to each other via multiple chemical bonds – in order to limit free rotation of monomers – and if the polymer chains are mainly constituted of aromatic groups
- High free volume in order to favor the permeation of the fastest permeating compound

Facilitated Transport Membranes

Initially, academic research on ionic metal olefin-selective facilitated transport membranes was focused on *liquid membranes*, whether immobilized liquid membranes containing silver nitrate (Teramoto et al. 1989; Ravanchi et al. 2009) or solvent-swollen membranes (Yang and Hsiue 1996). The selectivity of this type of membrane materials is based on a reversible specific interaction of the pi electrons of olefins with certain metal ions, such as ionic silver, dissolved in the polymer matrix, which results in facilitated olefin transport of the ion-olefin coupling through the membrane. Though offering good olefin/paraffin separation performances at lab scale, those materials were subject to a loss of solvent by evaporation, which resulted in dramatic fall of olefin/paraffin separation performances.

In the latter years, new attention was paid at promising ionic silver-impregnated *solid-state polyelectrolyte membranes* based on PVP, PAZ, or PEO polymer which were not suffering from desiccation phenomena when flowing dry gases (Kim et al. 2002). Though the first results based on pure compounds were very promising, i.e., an ideal separation propylene/propane factor as high as 15,000 (Kim et al. 2002), the mixed selectivity of those types of materials was lower by orders of magnitude (Kim et al. 2003). This significant discrepancy between the ideal and the mixture could be mainly attributed to a swelling-induced plasticization of the membrane materials by short olefins and paraffins (Ko et al. 2009).

Carbon Membranes

Carbon membranes are prepared by pyrolyzing polymeric precursors. The pyrolysis aims at (1) enhancing the molecular sieving properties of the processed polymer and (2) rendering them less sensitive to plasticization. When they are carbonized at high temperatures, the polymer chains tend to transform to an inorganic structure and the transfer mechanism of sorbents inside the

membrane materials switches from a solution-diffusion mechanism to a molecular sieving mechanism.

The main limit of carbon membranes is their *brittleness*, resulting practically in a poor mechanical strength (Yoshino et al. 2003). Several authors managed to keep the pyrolyzed membrane materials flexible by incorporating pendant sulfonic acid groups in the precursor polymer and keeping the pyrolysis temperature sufficiently low in order to allow the decomposition of the sulfonic acid groups without decomposing the skeleton of the polymer matrix (Islam et al. 2005).

Zeolite Membranes

Several studies concerning the separation of propylene from propane base on faujasite (FAU zeolite) membranes (Nikolakis et al. 2001) or titanosilicate ETS (Tiscornia et al. 2008) have been published recently. The olefin/paraffin selectivity of all those materials was comparable to glassy polymers and always below 10.

Olive Mill Wastewater Treatment by Membrane Operations

Alfredo Cassano

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The extraction of olive oil generates huge quantities of wastes having a great impact on land and water environments because of their high phytotoxicity. Pressure and three-phase centrifugation systems produce a liquid effluent called olive mill wastewater (OMW).

Olive Mill Wastewater Treatment by Membrane Operations, Fig. 1 Integrated membrane process for the treatment of OMWs

Several waste management approaches, including physicochemical treatments (natural evaporation, treatment with lime and clay, oxidation), agronomic methods (land spreading), animal breeding, and biological treatments (both aerobic and anaerobic) have been proposed to reduce the polluting load and, consequently, the final waste disposal. The efficiency of the process, the complexity, and the costs involved may vary remarkably. In addition, different legislations existing in olive-oil producing countries play an important role in the selection of appropriated technologies.

Pressure-driven membrane operations, including microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO) have been proposed and combined in integrated processes to obtain effluent streams from OMWs of acceptable quality for safe disposal into the environment (surface water or soil) for irrigation or even for recycling and use in the olive mill. Basically, MF and UF processes are used for primary treatment purpose, while NF and RO are used for final treatment (Cassano et al. 2013; Paraskeva et al. 2007).

Integrated systems based on the use of these processes permit to obtain a COD reduction of about 99 %, the recovery of high percentage of purified water (60–70 %) (permeate of RO membranes), a production of an organic fraction

(retentate of MF and UF membranes) which can be submitted to anaerobic digestion for the production of biogas, the recovery of a phenolic fraction (retentate of NF and RO membranes) of potential interest for food, phytoterapeutic, or cosmetic applications (Fig. 1).

Olive Wastewater

Alfredo Cassano
Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Olive oil extraction processes are usually grouped into press extraction and centrifugation extraction

Olive Wastewater,**Fig. 1** Scheme of OMWs treatment with UF membranes

systems (two-phase and three-phase centrifugal olive oil extraction).

The extraction of olive oil generates huge quantities of wastes having a great impact on land and water environments because of their high phytotoxicity. Pressure and three-phase centrifugation systems produce a liquid effluent called olive mill wastewater (OMW) or vegetation water. Typically, 0.5–1.5 m³ of OMWs per 1,000 kg of olives are produced depending on the process used. OMWs appear like violet-dark brown liquids with acid reaction (pH from 3 to 6) containing great quantity of suspended matter, high degree of organic pollution (COD, 40–220 g/L; BOD, 35–110 g/L), high electrical conductivity, reducing sugars up to 60 % of the dry substance and polyphenols (0.5–24 g/L) (Takac and Karakaya 2009).

The organic content is mainly represented by polyphenols, carbohydrates, polysaccharides, sugars, nitro compounds, polyalcohols, and oil.

Ultrafiltration (UF) membranes allow to separate macromolecules and colloids having molecular weight between 500 and 250,000 Da; they can be used to remove most parts of COD from pretreated OMWs producing a permeate stream which can be submitted to a biological treatment to comply with law limits relevant to BOD and COD (Borsani and Ferrando 1996). A scheme of

OMW treatment including a concentration step via UF is depicted in Fig. 1.

Open-Loop Cascade Diafiltration

Greg Foley

School of Biotechnology, Dublin City University, Dublin, Ireland

The configuration for open-loop cascade diafiltration is shown below. The product recovery is maximized in the first stage using constant volume diafiltration and concentrated in the second stage by ultrafiltration. Ideally, the rejection coefficient of the product is zero in the first stage and 1.0 in the second stage. In the closed-loop

Open-Loop Cascade Diafiltration,

Fig. 1 Open-Loop
Cascade Diafiltration

configuration, the permeate from the second stage is used as diluant for the first stage (Fig. 1).

Optimal Process Control

Radoslav Paulen

Department of Biochemical and Chemical
Engineering, Technische Universität Dortmund,
Dortmund, Germany

Efficient automatic control system is an essential part of every plant being operated in chemical industry. It may be implemented for various reasons: plant and environmental safety, fulfillment of varying process demands, rejection of input disturbances, optimal production desire, etc.

Process control is usually achieved via feedback policy. By measuring time-varying process outputs $\mathbf{y}(t)$ (controlled variables), such as temperature or concentration, one decides about process inputs $\mathbf{u}(t)$ (manipulated variables), such as input power to heating cell or valve position, to attain some or all of the abovementioned goals.

Classical control theory defines a fashion in which obtained measurements are used to identify values of inputs as a control law (Skogestad and Postlethwaite 2005). Its basic form can be stated as

$$\mathbf{u}(t) = f(\mathbf{y}(t))$$

$\mathbf{u}(t) = f(\mathbf{y}(t))$ where $f(\cdot)$ represents a function which can take various forms and can be designed

using analytical or numerical methods in order to establish optimal, adaptive, robust, stochastic, or any other type of process control.

Optimality of the process is measured in terms of performance criterion $J(\mathbf{y}, \mathbf{u})$. Optimal control of the process should be then set such that it minimizes this criterion. Classical problems of optimal control involve problems such as reference tracking or optimal change over control.

The most common reference tracking problem is expressed by

$$\min_{\mathbf{u}} \int_0^{\infty} (\mathbf{y} - \mathbf{y}^{ref})^T \mathbf{Q}(\mathbf{y} - \mathbf{y}^{ref}) + \mathbf{u}^T \mathbf{R} \mathbf{u} dt$$

where $\mathbf{y}^{ref}$ represents output reference (trajectory) and $\mathbf{Q}$ and $\mathbf{R}$ are so-called weighing matrices (Mikles and Fikar 2007). If this problem is considered and the controlled process is described by linear model (e.g., transfer function), function $f(\cdot)$ takes the form of a matrix-vector product, $\mathbf{K}\mathbf{y}$. Matrix $\mathbf{K}$ can be found easily using the tools of linear algebra. However, if the controlled system exhibits nonlinear behavior, more complicated techniques (e.g., dynamic optimization) are required.

Organic Acids Recovery by Nanofiltration

B. S. Ooi

School of Chemical Engineering, Universiti Sains Malaysia, Nibong Tebal, Pulau Pinang, Malaysia

Nanofiltration (NF) is a type of pressure-driven membrane that separates solute based on the size as well as charge exclusion. A negatively charged membrane is used to repel anionic organic acid

such as lactic acid, acetic acid, citric acid, amino acid, formic acid, and oxalic acid while allowing the uncharged solutes like sugar to pass through (Fig. 1). However, if the membrane is positively charged, the adverse phenomenon will be observed. NF for organic acid recovery is always regarded as a green biorefinery method due to its low energy consumption and unique separation properties, for example, nanofiltrations can be used as a method to separate lactic acid from the nutrients, salt, and unreacted carbon in fermentation broth; thus it combines production and purification of the organic acid in a single operation unit. Commercial nanofiltration such as Osmonics (DK, DL, HL), Hydranautics (HT), Filmtec (FT), Sepro (NF2, NF3, NF20), and Koch (KO) with molecular weight cutoff of 100–350 Da are usually employed.

The retention and separation of organic acid using nanofiltration is highly dependent on solution pH, diffusivity, temperature, and pressure. The suitability of NF membrane for the separation of organic acid from fermentation broth was based on the compromise between the rejection efficiency with the targeted permeation fluxes. NF membranes are usually employed after microfiltration membranes pretreatment for cell removal. In a laboratory trial, an NF composite polyamide membrane was found to retain more than 90 % of the unconverted sugars while allowing more or less 30 % lactic acid to permeate

Organic Acids Recovery by Nanofiltration,

Fig. 1 Nanofiltration for organic acid recovery

the membrane at a flux around $110 \text{ Lm}^{-2} \text{ h}^{-1}$ at pH 5.5, temperature 37°C , and transmembrane pressure of 13 bars (Sikder et al. 2012). Recovery of lactic acid from the fermentation broth is normally achieved using the hybrid NF and electro-dialysis system whereby sodium lactate is isolated from the fermentation broth using nanofiltration and then converted to lactic acid in the electro-dialysis stage.

In organic acid recovery using nanofiltration, the efficiency of the system is measured as separation factor, $\alpha = \frac{1-R_{\text{OA}}}{1-R_{\text{IM}}}$ where R_{OA} and R_{IM} are the rejection of organic acid and impurities, respectively. In a pilot scale test using Desal-5 DK membrane, the maximum separation factor of acetic acid over arabinose was 52, when the system was operated at pH 2.9 and an applied pressure of 24.5–34.3 bar (Weng et al. 2010).

In food industry, removal of benzoic acid (preservative) from citric acid in the fruit juice was also reported. At pH 4.5, benzoic acid is uncharged and shows negative rejection (highly permeable) compared to other organic acids in the fruit juice which enable its potential recovery.

Organic Dehydration

Tadashi Uragami

Organization for Research and Development of Innovative Science and Technology (ORDIST), Kansai University, Suita, Osaka, Japan

Water/organic-selective membranes are effective for the dehydration of water/organic mixtures.

Organic Dehydration, Fig. 1 Effects of the temperature of the membrane surroundings on the characteristics of permeation and separation for an aqueous solution of 50 wt.% dimethyl sulfoxide (DMSO) through the Chito membrane in TDEV. Feed temperature: 40°C

The dehydrated organic solvents can be useful as industrial reaction solvents, washing solvents, and analytical solvents.

In Fig. 1, the permeation and separation characteristics for an aqueous dimethyl sulfoxide (DMSO) solution through a dense chitosan (Chito) membrane by TDEV (see “► [Temperature-Difference-Controlled Evaporation \(TDEV\)](#)”) are shown. In this figure, the feed was an aqueous solution of 50 wt.% dimethyl sulfoxide, the temperature of the feed solution was kept constant at 40°C , and the temperature of the membrane surroundings was lowered to less than the temperature of the feed solution (Uragami and Shinomiya 1992). Both the total permeation rate and the separation factor increased with dropping temperature of the membrane surroundings. This increase in the total permeation rate may be due to the increase in the solubility of the vapor in the membrane with decreasing temperature of the membrane surroundings, according to Henry’s law. The increase of the separation factor, i.e., the improvement of the $\text{H}_2\text{O}/\text{DMSO}$ selectivity, can be explained by the illustration shown in Fig. 2.

When the dimethyl sulfoxide and water molecules which had vaporized from the feed mixture come close to the membrane surroundings, the

Organic Dehydration, Fig. 2 Tentative separation mechanism for aqueous dimethyl sulfoxide solution through a Chito membrane in TDEV

dimethyl sulfoxide vapor aggregates much easier than the water vapor (because the freezing points of dimethyl sulfoxide and water are 18.4 °C and 0 °C, respectively) and tends to liquefy as the temperature of the surrounding membrane becomes lower. This aggregation of the dimethyl sulfoxide molecules is responsible for the increase in the H₂O/DMSO selectivity for water through the Chito membrane. The increase in the separation factor with the TDEV method, in which the temperature of the membrane surroundings is lower than the temperature of the feed solution, can be attributed to the degree of aggregation of the DMSO molecule, which is significantly governed by the temperature of the membrane surroundings. The high H₂O/DMSO selectivity of Chito membrane for an aqueous solution dimethyl sulfoxide in TDEV is significantly enhanced by both the high affinity for water of the Chito membrane and the decrease in the solubility selectivity for dimethyl sulfoxide molecules into the Chito membrane, based on their aggregation on the membrane surroundings (Uragami and Shinomiya 1992; Uragami 2008). The mechanism of permeation and separation of a dimethyl sulfoxide/water mixture through a dense Chito membrane during TDEV in Fig. 2 is effective for

understanding that of an ethanol/water mixture through a dense PDMS membrane during TDEV (Uragami 2008).

The characteristics of permeation and separation of acetic acid/water mixtures through 85/15 (v/v) PVA/malic acid (MA) membranes were investigated by EV (see “► [Evapomeation \(EV\)](#)”) and TDEV. The permeation rates increased, but separation factors for H₂O/CH₃COOH selectivity decreased with increasing permeation temperature during EV. When the temperature of feed liquid was kept constant and the temperature of the membrane surrounding was dropped, the permeation rate and separation factor for H₂O/CH₃COOH selectivity were significantly influenced by the temperature of membrane surroundings. The increase in the acetic acid concentration in the feed vapor mixture decreased the permeation rate and increased the separation factor for H₂O/CH₃COOH selectivity except 40 wt.% acetic acid content. The best separation factors were 800 in the EV and 860 in the TDEV for 90 wt.% acetic acid. The separation index of TDEV was higher than that of EV for an azeotropic mixture of acetic acid/water. TDEV in the separation of acetic acid/water mixtures through the PVA/MA membranes was more effective than EV (Isiklan and Sanli 2005).

Graft-copolymer membranes grafted 4-vinyl pyridine, acrylonitrile, and hydroxymethyl methacrylate onto poly(vinyl alcohol) and also were applied to the dehydration of acetic acid in EV and TDEV, and those membranes showed high dehydration performance (Asman and Sanli 2006; Al-Ghezawi and Sanli 2006).

Water/alcohol-selective membranes are effective for the following scenario. For example, when an aqueous solution of dilute ethanol (about 10 wt.%) produced by the bio-fermentation is concentrated by distillation, since an aqueous solution of 96.5 wt.% ethanol is an azeotropic mixture, ethanol cannot be concentrated anymore by distillation, and consequently, ethanol is concentrated by azeotropic distillation with the addition of benzene. If membranes that can preferentially permeate only water at 3.5 wt.% in an azeotropic mixture of aqueous ethanol solution can be developed, significant energy savings

would be achieved. The permeation and separation mechanisms in PV, EV, and TDEV through dense membranes consist of the dissolution of the permeants into the membrane, the diffusion of the permeants in the membrane, and the evaporation of the permeants from the membrane. Therefore, the separation of permeants in the membrane separation techniques depends on the differences in the solubility and diffusivity of the permeants in the feed mixture. When the structure of water/alcohol- and water/organic liquid-selective membranes is dominically designed, hydrophilic materials can be recommended as membrane materials. Therefore, an increase in the solubility of water molecules into the membrane during the solution process can be expected. In order to raise the affinity of membranes for water molecules, membranes with dissociation groups introduced into their structure are used for dehydration from organic solvents.

The dehydration of an ethanol/water azeotrope during EV using polyion complex cross-linked chitosan composite (q-Chito-PEO acid PIC/PES composite) membranes, constructed from quaternized chitosan (q-Chito) and polyethylene oxydiglycolic acid (PEO acid) on a porous polyethersulfone (PES) support, was investigated (Uragami and Yamada 1999, 2003). Both the q-Chito/PES composite and the q-Chito-PEO acid polyion complex/PES composite membranes showed high H₂O/EtOH selectivity for an ethanol/water azeotrope. Both the permeation rate and the H₂O/EtOH selectivity were enhanced by increasing the degree of quaternization of the chitosan molecule, because the affinity of the q-Chito/PES composite membranes for water was increased by introducing a quaternized ammonium group into the chitosan molecule. Q-Chito-PEO acid PIC/PES composite membranes prepared from an equimolar ratio of carboxylate groups in the PEO acid versus quaternized ammonium groups in the q-Chito showed the best separation factor for H₂O/EtOH selectivity without lowering the permeation rate, as shown in Fig. 3. With an increasing molecular weight of PEO acid, the separation factor for H₂O/EtOH selectivity increased, but the permeation rate almost did not change. The separation factor

Organic Dehydration, Fig. 3 Permeation and separation characteristics for an azeotropic mixture of ethanol/water through q-Chito/PEO acid 4000 polyion complex/PES composite membranes during EV as a function of the molar ratio between the carboxylate groups in PEO acid 4000 and the ammonium groups in q-Chito at 40 °C

for aqueous solutions of 1- and 2-propanol was also maximized at an equimolar ratio of carboxylate groups and ammonium groups and was greater than for an ethanol/water azeotrope.

Hacettepe University, Ankara, Turkey

Antibodies exhibit unique binding properties, high affinity and specificity towards a wide range of natural and synthetic targets. Because of these properties, antibodies are utilized in many applications including therapeutics, diagnostics, research in biology and biotechnology, immunoaffinity chromatography, etc. (Huse et al. 2002). For medical applications, immunoglobulins (IgGs) have been purified using a combination of various methods like precipitation and chromatographic techniques including hydrophobic interaction, histidine affinity, ion exchange, dye affinity, and metal-chelate affinity

(Tishchenko et al. 2002; Yavuz and Denizli 2005; Denizli 2011). Antibody immobilization is an important step in the preparation of chromatographic immunoaffinity column. The recognition part of the antibody has to be accessible to maintain the antibody's functionality and to detect the analyte molecule. Therefore, during immobilization, the proper orientation of antibodies on the surface of the solid support is crucial (Batalla et al. 2008). There are some more specific techniques using immobilized protein A or G for the immobilization of antibodies by the F_c region. These are more efficient techniques resulting to the oriented immobilization of antibodies and thus giving rise to highly accessible antigen-binding sites on the antibody and increase in the activity of the immobilized antibody molecule (Hober et al. 2007). However, despite their general use as effective ligands for the oriented immobilization of antibodies, they have some drawbacks in their economical value, reusability, and concerns over the clearance of leached ligand (Low et al. 2007). Small antibody fragments can be evaluated as simple, inexpensive, more stable, general purpose ligands to be an alternative to protein A or G. In combination with an oriented immobilization method, these small antibody fragments allow an increased degree of immobilization of well-oriented and active antibodies per solid support surface area, hence facilitating higher antibody-antigen complex formation (Bonroy et al. 2006). Fc fragment-imprinted poly(hydroxyethyl methacrylate) cryogel (MIP) can be used for the oriented immobilization of anti-hIgG for IgG purification from human plasma. Non-imprinted poly(hydroxyethyl methacrylate) cryogel (NIP) can be also used for random immobilization of anti-hIgG to compare the adsorption capacities of oriented (MIP/anti-hIgG) and random (NIP/anti-hIgG) cryogel columns. IgG adsorption capacity is found to be three times higher than the NIP/anti-hIgG column (29.7 mg/g) for the MIP/anti-hIgG column (86.9 mg/g) (Fig. 1). Higher IgG adsorption capacity was observed from human plasma (up to 106.4 mg/g) with the MIP/anti-hIgG cryogel column. The results obtained are promising and show that F_c fragments of antibodies with

Oriented Immobilized Anti-hIgG via Fc Fragment-Imprinted Cryogels, Fig. 1

IgG adsorption amounts of MIP/anti-hIgG (oriented) and NIP/anti-hIgG (random) cryogel (Bereili et al. 2013)

an oriented immobilization method can be considered as a potential candidate for IgG purification human plasma (Bereili et al. 2013).

Orthogonal Collocation Method

Radoslav Paulen

Department of Biochemical and Chemical Engineering, Technische Universität Dortmund, Dortmund, Germany

This method represents an approximation technique which is successfully used to solve multipoint boundary value problems. Such problems arise in engineering applications frequently when it is desired to simulate processes described by partial differential equations (Kaldis et al. 2000; Sousa and Mendes 2004), to model complex processes (Ganguly and Bhattacharya (1994); Sousa et al. 2002) or to compute optimal process control (Fikar et al. 2010).

The principle is to approximate the behavior of any nonlinear function $f(\mathbf{x})$ by the sum of basis functions (most preferably polynomials) on some chosen number of intervals. Approximation function on the k th interval, Y^k , can be written as

Orthogonal Collocation Method, Fig. 1 Schematic representation of orthogonal collocation method

$$\mathbf{Y}^k(\mathbf{y}^k, x) = \sum_{i=0}^{N_p} y_i^k \phi_i^k(x)$$

where $\mathbf{y}^k$ is a vector of N_p+1 collocation points which represent weighting factors (coefficients) for vector of functions ϕ^k . If polynomial approximation is considered, function ϕ_i^k is an N_p th order polynomial. To guarantee the orthogonality of resulting approximation and to achieve other useful properties, orthogonal polynomials (such as Chebyshev, Lagrange, and other types) are used. For the case of Lagrange polynomials, function ϕ_i^k can be written as follows:

$$\phi_i^k(x) = \prod_{j=0, j \neq i}^{N_p} \frac{x - x_j^k}{x_i^k - x_j^k}.$$

This is illustrated in Fig. 1 which shows three consecutive intervals of approximation.

Overall Permeation Reduction Coefficient

Alessio Caravella

National Institute of Advanced Industrial Science and Technology – Research Institute for Innovation in Sustainable Chemistry, ISC-AIST, Tsukuba, Ibaraki, Japan

Overall permeation reduction coefficient. In *membrane technology*, the so-called overall permeation reduction coefficient (*PRC*) refers to a coefficient indicating quantitatively the overall reduction of permeability (or, equivalently, reduction of permeance or flux) of a species because of the concurrent actions of different phenomena, like, as the most common instances,

concentration polarization and *inhibition*. The most general definition of PRC can be provided as follows:

$$[\text{Flux}]_i^{\text{Actual}} = (1 - PRC_i) \times [\text{Flux}]_i^{\text{Max}} \quad (1)$$

Equation 1 simply states that the actual flux (i.e., in the presence of phenomena reducing membrane performance) is equal to the product of the maximum flux (i.e., free of unwanted phenomena) by a certain reduction factor. According to this definition, PRC_i approaches the unity value (flux tending to zero) when the unwanted phenomena control permeation, whereas it approaches zero when those phenomena are negligible.

If considering that the overall permeation reduction is due to the coupled effect of *concentration polarization* and *inhibition*, then, under the validity of Henry's law hypotheses for the inhibiting species, PRC_i can be expressed as a function of both CPC_i and IC_i as (Caravella et al. 2010):

$$PRC_i = 1 - (1 - CPC_i)(1 - IC_i) \quad (2)$$

where CPC_i and IC_i are the *concentration polarization coefficient* and the *inhibition coefficient*, respectively.

Oxidative Coupling in Membrane Reactors

Juergen Caro
Institute of Physical Chemistry and
Electrochemistry, Leibniz University, Hannover,
Germany

Oxidative coupling of methane according to
 $2\text{CH}_4 + \text{O}_2 \rightarrow \text{C}_2\text{H}_4 + 2\text{H}_2\text{O}$ is a promising

way to transform natural gas into ethylene and ethane. From numerous classical co-feed experiments in packed bed reactors it follows that for a high C_2 selectivity of about 70 %, the CH_4/O_2 ratio must be high. To ensure a high C_2 selectivity, the reaction has to be performed at low oxygen partial pressure. This situation can be ensured by applying the concept of distributed oxygen dosing in “membrane distributor reactor” with dense (perovskite-like ceramic, silver) or porous membranes. The accepted reaction mechanism assumes as first step the formation of CH_3 radicals on a heterogeneous catalyst. After this heterogeneous step, the combination of two CH_3 radicals to ethane is proposed in a homogeneous gas phase reaction, followed by an oxidodehydrogenation of the ethane to ethylene. This reaction chain can be realized in a catalytic membrane reactor with oxygen supply from surrounding air applying established heterogeneous catalysts like 2 wt% Mn/5 wt% Na_2WO_4 on SiO_2 for the CH_3 formation (Kondratenko and Baerns 2008). By supplying the oxygen through the reactor wall, a rather low and constant oxygen partial pressure in axial direction of a tubular reactor can be achieved which should be beneficial for selectivity. Hot spots and explosive mixtures – like often observed for co-feed reactors – can be avoided in the case of the membrane distributor reactor (Dittmeyer and Caro 2008; Caro 2010). However, whereas best C_2 yields in classical packed bed reactors with an oxygen/methane co-feed reach 30 %, best membrane reactor data are of the order of 15 % (Tan and Li 2006) or 17 % (Czuprat et al. 2010).

Oxidative Steam Reforming

Fausto Gallucci

Chemical Process Intensification, Department of Chemical Engineering and Chemistry, Eindhoven University of Technology, Eindhoven, The Netherlands

Autothermal reforming or oxidative steam reforming is a combination of conventional steam reforming of the fuel (endothermic reaction) with the partial oxidation of a small amount of the fuel (exothermic reaction) in order to achieve an autothermal reaction that proceeds without external input of energy.

The most studied autothermal reforming is the conversion of methane to hydrogen. The overall chemical reactions taking place in the autothermal reforming of methane include steam reforming (Eq. 1), water-gas shift (Eq. 2), and total oxidation (Eq. 3). The energy generated by the oxidation reaction and WGS is used for the SMR:

This reaction system can be carried out efficiently in a membrane reactor as the extraction of hydrogen during the reaction shifts the equilibrium reactions toward completion at moderate temperatures, and thus the extent of oxidation reaction to achieve autothermal reforming is moderate.

One of the problems of autothermal reforming carried out in membrane reactors is the mismatch between the oxidation reaction rate and the reforming reaction rate. The oxidation is often much faster than the reforming, and for this reason, in packed bed membrane reactors, a high temperature region is obtained at the beginning of the bed followed by a low temperature region at the end of the bed. This could cause problems to the membranes that could be damaged by high temperatures while does not work properly (low

flux – see Richardson equation) at lower temperatures.

To circumvent these problems, fluidized bed membrane reactors are often proposed for this kind of reaction system, as the solid circulation inside the reactor allows a virtually isothermal condition even in case of highly exothermic reactions.

Examples of autothermal reforming (ATR) (or oxidative steam reforming) reactions also include the ATR of ethanol and methanol or the ATR of naphtha. All these reactions have been successfully tested in membrane reactors for pure hydrogen production.

Oxyfuel

[Oxyfuel combustion](#)

The name is derived from the process: a mixture of oxygen and a gaseous, liquid, or solid fuel is burnt in a nitrogen-free atmosphere which consists of oxygen and an easy to separate second gas, usually carbon dioxide. If fuels like natural gas, oil, or coal are combusted with pure oxygen instead of air as oxidant, nitrogen as an inert component is not heated. Therefore, the burning unit can be smaller, the flame temperatures are higher, and the fuel consumption is reduced. Depending on the fuel, the flue gas consists of CO_2 and H_2O only. After condensation of H_2O , the flue gas consists of only CO_2 which can be sequestered or used in chemical processes. But not only the mass and volume of the flue gas become smaller, due to the absence of nitrogen, also no NO_x is formed.

The oxyfuel combustion process is one of several possible technologies to separate and

sequester CO_2 from fossil fuel burning especially in electric power stations. However, electricity generation by the oxyfuel process is more expensive than in a traditional air-fired plant. The main cost factor of the oxyfuel process is the production of almost pure oxygen. Perovskite-type mixed conducting ceramics can theoretically separate oxygen with 100 % purity from air. Some of the CO_2 is in a loop used for sweeping the oxygen from the membrane separator to the combustion chamber thus reducing the oxygen partial pressure on the permeate side of the membrane to have a constant high driving force for oxygen permeation. This sweeping technique with some of the CO_2 in a loop requires CO_2 -stable oxygen-conducting membranes. Since most of the mixed conducting perovskite-type ceramics contain alkaline earth metal cations, these materials are not suitable since they form carbonates (for thermodynamic reasons also at high temperatures because of the high CO_2 partial pressure). Therefore, new CO_2 -stable mixed conducting or dual-phase materials have to be developed.

Since the fuel is combusted in an O_2/CO_2 atm, this combustion with diluted oxygen reduces the flame temperature which reduces the costs for special high temperature-resistant materials. The amount of the second inert gas can control the flame temperature of the combustion: Without any dilution gas, the combustion temperature can become too high. On the other hand, if the CO_2 concentration is much less than 80 % (nitrogen content of air), higher flame temperatures can be reached which is desired.

However, the few pilot plants evaluating the feasibility of the oxyfuel concept use oxygen production by cryogenic air separation after Linde (Callide Oxyfuel Project; Callide Oxyfuel Pilot Project; CCS Vattenfall Pilot Oxyfuel Project). In 2006 in the Schwarze Pumpe industrial area in East Germany, construction work started on the world's first "carbon-dioxide free" power station testing the oxyfuel concept on a pilot scale. However, the owner Vattenfall stopped carbon capture R&D at the plant in 2014 because "its costs and the energy it requires makes the technology unviable" ([http://www.thelocal.se/20140507/vattenfall-abandons-research-on-co2-](http://www.thelocal.se/20140507/vattenfall-abandons-research-on-co2-storage)

[storage](#)). In the Callide oxyfuel project, carbon dioxide capture started in Dec. 2012. In March 2015, the Callide Oxyfuel Project demonstration phase comes to a close after 2 years and 9 months successfully proving 10,000 h of oxyfuel combustion, and 5,500 h of carbon dioxide plant operation. Since the usual oxygen purity of 99.5 % as obtained in the Linde technique is not necessary for oxyfuel, the Linde technology can produce oxygen with 95 % purity in a cost-effective way which is competing with the ceramic membrane technology. Organic polymer membrane permeation is not competitive since it cannot produce the necessary oxygen purity of ≥ 95 % purity in a single step.

Air separation

Oxygen can be separated from air by different separation techniques such as cryogenic air distillation after Linde, pressure swing adsorption using coals for kinetic separation (the slightly

Oxygen Separation, Fig. 1 Photo and scheme of the three-tube oxygen production demonstration unit at Leibniz University of Hannover (copyright Caro, Univ. Hannover). Oxygen from surrounding air enters the BCFZ material on the shell side, diffuses via vacancies in the

oxygen lattice to the core side of the one-end-sealed BSCF tubes where it is released into the gas phase. To have a high-oxygen partial pressure difference over the membrane, the permeated oxygen is removed by vacuum pumping

smaller oxygen diffuses faster than nitrogen into the pores of the coal), or Li-exchanged zeolites like Li-LTA/Li-FAU for thermodynamically controlled separation (the more polar nitrogen is strongly adsorbed by the zeolite than the less polar oxygen). Also organic polymer hollow fiber membranes are used for oxygen/nitrogen separation, but they produce in general lower gas purity. The amount and purity of the oxygen to be produced decides about the economy of the separation techniques to be applied.

Perovskite membranes allow principally a new route for oxygen separation from air, however, at elevated temperatures of 750 °C to 900 °C. The high temperatures are necessary for a high-oxygen ion mobility and to avoid membrane damage (if CO₂ is present in low concentrations, carbonates do not form at high temperatures, see Ellingham diagram). As long as there is a sufficient gradient of the oxygen partial pressure (better: activity) over the membrane, oxygen will enter the perovskite material on the high-oxygen partial pressure side (feed side) and leave the

membrane on the low-oxygen partial pressure side (permeate side). The low-oxygen partial pressure can be achieved by continuous vacuum pumping as the most effective and economic technique but also with sweep gases. In the latter case, the sweep gases and oxygen must be separated again (if steam is used, the membrane can be damaged at the high permeation temperature). Another option to reduce the oxygen partial pressure on the permeate side is the consumption of the permeated oxygen in a catalytic partial oxidation (e.g., by consuming oxygen in a methane partial oxidation to synthesis gas).

Figure 1 shows a three-tube perovskite membrane module with 1 cm (outer diameter) Ba_{0.5}Sr_{0.5}Co_{0.8}Fe_{0.2}O_{3-δ} (BSCF) tubes purchased from Fraunhofer IKTS (Fraunhofer Institute for Ceramic Technologies and Systems, Dresden-Hermsdorf, Germany). The permeator has been erected during November 2012–April 2013 at Leibniz University of Hannover copying a prototype oxygen separation permeator developed by Dr. R. Kriegel (Fraunhofer IKTS, Hermsdorf)

(Kriegel et al. 2010; Schulz et al. 2011). The permeator is gastight up to an operation temperature of 950 °C, membrane area 400 cm², and dead-end BSCF tubes.

Oxygen Transport Ceramic Membranes: Perovskite and Nonperovskite

Vesna Middelkoop
Flemish Institute for Technological
Research – VITO, Mol, Belgium

Current State of Oxygen Transport Ceramic Membranes Development

For more than a decade, there has been considerable interest in dense inorganic (ceramic) oxygen separation membranes as they offer a potentially

attractive means of producing high-purity oxygen from air for use in the next generation of industrial processes and clean energy applications. Such applications are centered around oxy-combustion, coal gasification (membranes are integrated as power plant components, see example in Fig. 1), or commercial chemical reactions for conversion of natural gas and production of syngas and hydrocarbons (membranes are integrated as catalytic membrane reactors) in addition to the development of electrochemical devices (solid oxide fuel cells, SOFC) utilizing thin dense membranes of oxygen ion conductor (Dong and Jin 2012; Dong et al. 2011; Hashim et al. 2011; Thursfield and Metcalfe 2004; Skinner and Kilner 2003).

This class of membranes is often referred to in the literature as oxygen transport membranes (OTM) or ion transport membranes (ITM). Currently at the forefront of the development and deployment of oxygen producing membrane-based systems are a couple of large-scale funded programs worldwide such as the EC Seventh Framework Programs CARENA, DEMCAMER and HETMOC, and OXYCOAL-AC and MEM-BRAIN (Germany); US DOE's Vision 21 R&D Program; the Australian COAL21; the Japanese NEDO programs; and the "863" and "973" programs (national research and development programs in China) (<http://www.netl.doe.gov/technologies/coalpower/ewr/co2/oxy->

combustion/otm-based.html; <http://www.netl.doe.gov/technologies/coalpower/gasification/projects/gas-sep/40343.html>; Kneer et al. 2010).

Oxygen Transport Mechanism

These emerging approaches to oxygen separation rely on exploiting the unique properties of the materials that are fabricated into membranes. When they are thermally activated to sufficiently high temperatures (typically from 700 °C to 950 °C) and exposed to an oxygen partial pressure gradient, oxygen anions and electrons continuously migrate through the crystal lattice counter-currently with electrons (see Fig. 2).

Perovskite- and Non-perovskite-Based Membranes

A wide variety of mixed ionic-electronic conducting (MIEC) oxides for high-temperature membrane separation have been investigated alongside novel chemical doping, synthesis, and processing routes. All MIEC conductors that are being considered for this purpose fall into two main groups: perovskite-based oxides (both of the perovskite $\text{ABO}_{3-\delta}$ structure and perovskite-related oxides of the $\text{A}_2\text{BO}_{4+\delta}$ structure) and

fluorite-based oxides (i.e., non-perovskites of the $\text{A}_{\delta}\text{B}_{1-\delta}\text{O}_{2-\delta}$ and $\text{A}_{2-\delta}\text{B}_{2-\delta}\text{O}_3$ structures). Furthermore, dual-phases composite membranes (e.g., $\text{Ce}_{0.8}\text{Gd}_{0.15}\text{Cu}_{0.05}\text{O}_{2-\delta}$ - $\text{SrFeO}_{3-\delta}$, CGCO-SFO) can be considered as another possibility for oxygen separation by combining a perovskite oxide phase (as an oxygen ionic and electronic conductor) and fluorite oxide phase (as an oxygen ionic conductor) in order to accommodate the performance and durability requirements of the membrane (Sunarso et al. 2008; Fang et al. 2015).

One of the primary industrial requirements for efficient membrane-based processes is a sufficiently high transmembrane oxygen flux which is inversely proportional to membrane thickness. Moreover, taking into consideration a higher surface area to volume ratio, hollow fiber geometry is favored over planar or tubular membranes. When the oxygen permeation data with accompanying chemical and mechanical stability at elevated temperatures and under different atmospheres are compared, to date, the most promising and readily available among the oxygen transport membranes belong to the $\text{Ba}_x\text{Sr}_{1-x}\text{Co}_{1-x}\text{Fe}_y\text{O}_{3-\delta}$ and $\text{La}_x\text{Sr}_{1-x}\text{Co}_{1-y}\text{Fe}_y\text{O}_{3-\delta}$ perovskite families, namely, $\text{Ba}_{0.5}\text{Sr}_{0.5}\text{Co}_{0.8}\text{Fe}_{0.2}\text{O}_{3-\delta}$ (BSCF5582), $\text{BaZr}_x\text{Co}_y\text{Fe}_z\text{O}_{3-\delta}$ (BCFZ) and $\text{La}_{0.6}\text{Sr}_{0.4}\text{Co}_{0.2}\text{Fe}_{0.8}\text{O}_{3-\delta}$ (LSCF6428). The highest reported oxygen permeation fluxes are those of 0.3 mm thick BSCF5582 hollow fibers,

Oxygen Transport Ceramic Membranes: Perovskite and Nonperovskite,

Fig. 3 Highest reported oxygen flux values of BSCF5582 hollow fiber membrane as a function of temperature and sweep gas rate (Reproduced from Han et al. (2013) with permission from Elsevier)

Oxygen Transport Ceramic Membranes: Perovskite and Nonperovskite, Fig. 4 SEM cross section of a dense BCFZ perovskite hollow fiber with an outer diameter of 0.88 mm, wall thickness of 0.175 mm, 11.9 cm long, and a high mechanical stability of 175 ± 15 MPa. Oxygen

permeation flux through this BCFZ hollow fiber membrane was 7.6 ml/min/cm^2 at 900°C at a flow rate of 150 ml/min of air supplied to the shell side and a helium sweep of 30 ml/supplied to the core side of the fiber (Reproduced from Schiestel et al. (2005) with permission from Elsevier)

$11.46 \text{ mL min}^{-1} \text{ cm}^{-2}$ at 950°C and a helium sweep of 200 ml min^{-1} (see Fig. 3). The BCFZ hollow fibers (shown in Fig. 4) have slightly lower oxygen fluxes but offer greater long-term stability. LSCF6428 exhibits desirable chemical stability and mechanical strength but much lower fluxes than BSCF5582 and BCFZ (up to $1 \text{ mL min}^{-1} \text{ cm}^{-2}$) (Han et al. 2013; Schiestel

et al. 2005; Wang et al. 2009). However, it is worth noting that the chemical stability of Co-rich perovskites containing alkaline earth metals (typically BSCF5582) is affected in the presence of CO_2 (they tend to form carbonates) causing a decrease in flux (Arnold et al. 2007; Xu et al. 2012). On the other hand, some of the perovskite-related materials (such as

Oxygen Transport Ceramic Membranes: Perovskite and Nonperovskite, membrane ($J(O_2) \sim 0.16 \text{ mL min}^{-1} \text{ cm}^{-2}$): (a) cross section, (b) core side surface, (c) shell side surface, (d) and (e) are chemical compositions for spots 1 and 2, respectively. (Reproduced from Liu et al. (2012) with permission from Elsevier)

$\text{CaTi}_{0.8}\text{Fe}_{0.2}\text{O}_{3-\delta}$, $\text{La}_2\text{NiO}_{4+\delta}$ with fluxes up to $0.45 \text{ mL min}^{-1} \text{ cm}^{-2}$) (Klande et al. 2011) as well as non-perovskite types (e.g. $\text{Sr}_4\text{Fe}_4\text{Co}_4\text{O}_{13+\delta}$ with fluxes up to $0.30 \text{ mL min}^{-1} \text{ cm}^{-2}$) (Balachandran et al. 1995) and dual phase composite membranes provide relatively low fluxes (e.g., $\text{Ce}_{0.8}\text{Gd}_{0.2}\text{O}_{2-\delta}-\text{Gd}_{0.2}\text{Sr}_{0.8}\text{FeO}_{3-\delta}$, $\text{Ce}_{0.8}\text{Gd}_{0.15}\text{Cu}_{0.05}\text{O}_{2-\delta}-\text{SrFeO}_{3-\delta}$ and $\text{Ce}_{0.8}\text{Sm}_{0.2}\text{O}_{2-\delta}+\text{SrCO}_3+\text{Co}_3\text{O}_4$: 0.80, 0.84 and $93 \text{ mL min}^{-1} \text{ cm}^{-2}$ respectively) but they are found to have much greater structural and chemical stability in a reducing atmosphere (Zhu et al. 2008; Fang et al. 2015; Zhang et al. 2015).

Oxygen-Enriched Air (OEA) Production by Membrane Reactors

Juergen Caro

Institute of Physical Chemistry and

Electrochemistry, Leibniz University, Hannover, Germany

Air with increased oxygen content has different applications ranging from sub-aqua diving and medical treatments to processes like waste burning, FCC catalyst regeneration, preparation of synthesis gas for ammonia production, Claus plants, and high-temperature furnaces and kilns.

The reduction of the inert nitrogen as a ballast is of advantage in several processes. When increasing the oxygen content of air from 21 % to 30 %, there is 40 % less nitrogen per oxygen unit, and membranes of modest selectivity (3–5) and higher oxygen flux are preferred.

OEA can be produced by mixing air with pure oxygen from cryogenic air distillation after Linde or by pressure swing adsorption. Membranes can produce OEA in two different ways:

- (i) There exists a variety of commercial organic polymer membranes with a preferential oxygen transport. Since oxygen has a slightly smaller molecule size and it undergoes less interaction than the quadrupolar nitrogen, oxygen (plus carbon dioxide + water vapor) permeates faster through the polymer film than nitrogen and argon. This can be used to produce nitrogen as retentate on the high-pressure side and an oxygen-enriched air on the low pressure permeate side. If the target product is nitrogen on the high-pressure feed side, the oxygen-enriched permeate is called “waste gas.” It is estimated that for an oxygen purity of 30 % and a capacity $< 15,000 \text{ Nm}^3/\text{h}$, the investment, operating, and maintaining costs are two thirds to three fourths of cryogenic and PSA technology. Often, the spiral wound geometry is preferred and the pressure difference across the membrane is maintained

by a vacuum pump on the permeate or a compressor/van on the feed side (Puri 2011).

- (ii) Recently, perovskite-type high-temperature ceramic membranes have been proposed for OEA production (Liang and Caro 2011). Here the fee is slightly pressurized air of about 2 bar (O_2 partial pressure ≈ 0.4 bar). As sweep gas, air of typically 1 bar (O_2 partial pressure ≈ 0.2 bar) is applied. Because of the difference in oxygen partial pressure, there is an oxygen transport from the feed to the permeate side until the O_2 partial pressure on the permeate side also reaches 0.4 bar, which is air with 40 % O_2 at 1 bar (Wang et al. 2005; Hamel et al. 2006).

Packed Bed Membrane Reactor

Fausto Gallucci

Chemical Process Intensification, Department of
Chemical Engineering and Chemistry, Eindhoven
University of Technology, Eindhoven,
The Netherlands

The fixed bed (or packed bed) membrane reactor configuration is the first and most studied configuration for membrane reactors. This is because the first studies on membrane reactors focused on the effect of the gas permeation through membranes on the reaction system (which is often a conventional packed bed reactor).

In a packed bed membrane reactor, the catalyst is confined in fixed bed configuration, and it is in contact with a permselective membrane. The most used packed bed configuration is the tubular one where the catalyst may be packed either in the membrane tube or in the shell side, while the permeation stream is collected in the other side of the membrane (in case of hydrogen-selective membranes) or one reactant is feed on the other side of the membrane (in case of oxygen-selective membrane).

For multi-tubular membrane reactor configurations, the catalyst in tube configuration can be preferred especially for construction reason and for the extent of bed-to-wall mass and heat transfer limitations which can be very detrimental in the catalyst in shell configuration.

Often, a sweep gas can be used in the permeation side of the membrane in order to keep the permeation hydrogen partial pressure as low as possible for minimizing the membrane area required for the hydrogen separation. This practice is, for example, very useful if hydrogen for ammonia plant is being produced, in which case an amount of nitrogen can be used for sweeping the permeation side producing a synthesis stream ($N_2/H_2 = 1/3$) ready for the final reaction step. If a sweep gas is used in the permeation side, then a packed bed membrane reactor can be used in both cocurrent or counter-current modes.

An interesting feature of packed bed membrane reactors is the possibility to operate them in a reverse flow mode, integrating the reaction and separation with the recuperative heat exchange inside the reactor. This operational mode is quite interesting for partial oxidation of methane (POM) (Smit et al. 2005). In normal POM systems, air and CH_4 feed streams have to be preheated to the reaction temperature, while POM reaction being only slightly exothermic, the external heat transfer between feed and exhaust is very expensive. Therefore, recuperative heat exchange is preferably carried out inside the reactor.

Although the tube in tube configuration is quite useful to work in lab scale and for proof of principle of membrane reactors, for industrial scale some other configurations need to be used in order to increase the membrane area per volume

of vessel used. In fact, the amount of hydrogen produced is directly related to the amount of membrane area installed in the reactor. Starting for the tube in tube configuration, a straightforward way to increase the membrane area in packed bed is the tube in shell configuration (Buxbaum 2002; Tosti et al. 2008).

Although the packed bed configuration is very advantageous and easy to operate, the production of thin membranes brought under the spotlight one of the disadvantages of fixed bed membrane reactors: the influence of bed-to-wall mass transfer limitations on the membrane area required. Briefly, as long as the hydrogen flux through the membrane is a limiting step, the effect of external mass transfer limitations such as the limitations to hydrogen transport between the bulk of the catalytic bed (where hydrogen is produced) and the membrane wall (where hydrogen is recovered) can be neglected. However, by increasing the membrane flux, the external mass transfer limitations became limiting and determine the extent of membrane area. This has been demonstrated both experimentally (Peters et al. 2008) and numerically (Gallucci et al. 2010). This important drawback has driven the research toward new reactor concepts such as micromembrane reactors or fluidized bed membrane reactors.

Palladium-based membranes have received a growing interest for the separation and purification of hydrogen from various resources (Paglieri and Way 2002; Yun and Oyama 2011; Gallucci et al. 2013). In addition, palladium membranes can be used as a palladium-based membrane reactor where the separation process is coupled with catalytic reactions. Palladium-based membranes have advantages of high hydrogen flux and exclusive permselectivity for hydrogen due to the unique permeation mechanism as shown in Fig. 1.

General Aspects

The developments in Pd and Pd alloys have been carried out for a long time (Buxbaum 1999; Grashoff et al. 1983; Holleck 1970). The most important problem associated with the use of pure Pd membranes is the hydrogen embrittlement phenomenon. Operation with hydrogen at a temperature below 300 °C and a pressure below 2 MPa leads to the nucleation of the β -hydride phase from the α -phase resulting in severe lattice strains. In this case a pure palladium membrane becomes brittle after a few $\alpha \rightleftharpoons \beta$ cycles (Hsieh 1989). Another important problem is the palladium surface poisoning, which can be more significant for thin metal membranes, by sulfur compounds (Edlund and Pledger 1994), CO (Amandusson et al. 2000), H₂O (Li et al. 2000), chlorine, carbon, unsaturated hydrocarbons, etc. In order to avoid hydrogen embrittlement and poisoning and reduce membrane cost,

Palladium-Based Membrane (Palladium Alloy Membrane),

Fig. 1 Solution-diffusion mechanism of hydrogen permeation through a palladium-based membrane (Yun and Oyama 2011)

palladium can be alloyed with other metallic elements such as Ag, Cu, Fe, Ni, Pt, and Y (Bryden and Ying 2002; Qiao et al. 2010; Uemiyama et al. 2007), or the palladium grains can be used in nanometer sized (Pacheco Tanaka et al. 2006).

Palladium Alloys

Among binary palladium alloys, Pd-Ag, Pd-Cu, Pd-Au, Pd-Ce, and Pd-Y exhibit higher permeabilities in comparison to pure Pd, according to Knapton that tested 25 μm thick alloys (Knapton 1977). $\text{Pd}_{90}\text{Y}_{10}$ has hydrogen permeability 3.8 times higher than pure Pd at 350 $^{\circ}\text{C}$.

Some interesting palladium alloys to avoid embrittlement are $\text{Pd}_{77}\text{-Ag}_{23}$ and $\text{Pd}_{70}\text{-Pt}_{30}$ (weight%) alloys since their critical temperature (T_c) for formation of the β -phase is around room temperature (Paglieri and Way 2002). Besides, Pd-Cu alloys do not show embrittlement even at low temperatures (Kulpatirpanja et al. 2005).

Pd-Cu, Pd-Au, Pd-Pt, Pd-Rh, and Pd-Ru alloys have been used for increasing the tolerance to sulfur (Paglieri and Way 2002; Morreale et al. 2004; Way et al. 2008). According to McKinley, a $\text{Pd}_{60}\text{Au}_{40}$ (mass%) is superior to a $\text{Pd}_{60}\text{Cu}_{40}$ (mass%) concerning poisoning by sulfur (McKinley and Nitro 1967). According to Morreale et al., face-centered cubic (fcc) Pd-Cu showed a decline of 0–10 % permeability when exposed to 1,000 ppm of sulfur, and body-centered cubic (bcc) Pd-Cu showed a decline of 99 % at the same sulfur content stream (Morreale et al. 2004). Thus, the final structure of the

palladium alloy is an important issue. In general, the sulfides of Pt, Ir, Rh, and Ru are much less stable than those of the Pd, and thus these elements show better tolerance to poisoning by sulfur.

Currently, novel Pd-based ternary alloy membranes are being studied (Peters et al. 2011, 2013).

Unsupported and Supported Membranes

Unsupported Pd-based membranes need to be thick self-standing films ($>50 \mu\text{m}$ thick) in order to have a minimum mechanical stability. The main drawback of these membranes is their low hydrogen permeance. Moreover, in the case of using an expensive membrane material, the cost of the whole membrane will be sharply increased by increasing the membrane thickness. Thus, there is a threshold between membrane mechanical stability and membrane thickness (and thus flux and costs). For this reason it is foreseen that the first industrially available membranes will be supported membranes. Supported membranes consist of a thin selective film deposited onto a support that provides mechanical stability. Thus, the hydrogen permeance of the membrane will be higher so that less membrane area is required and the whole membrane cost will be lower than that for unsupported membranes. However, in the total membrane cost, the cost of the support also becomes important. Especially when very thin film membranes are selected, the support pore size should be much lower and the surface much

smoother, so that its cost will increase. There are mainly two types of porous support materials: metallic and ceramic. Ceramic supports typically have better surface quality providing membranes with thinner selective layers. However, they are more fragile. Metallic supports are more robust than ceramic, but the commercial ones, mainly tubular, have lower surface qualities. Some research groups are developing hollow fiber supports (both ceramic and metallic) in order to increase the surface area to volume ratio and also improve the surface quality (Luiten-Olieman et al. 2012). In the case of the Pd-based membrane, support is metallic and is used at temperatures above the Tamman temperature of one of the metallic parts, common situation for high-temperature reforming reactions; it is necessary to position an intermetallic diffusion barrier layer between the metallic support and the metallic selective layer. In this case the materials used as barrier layer are ZrO_2 (Tarditi et al. 2013), YSZ (Sanz et al. 2011), TiO_2 (Li et al. 2008), CeO_2 (Qiao et al. 2010), and Al_2O_3 (Dardas et al. 2009).

Palladium Membrane Preparation

Common Pd-based layer deposition technologies include physical vapor deposition (PVD, including magnetron sputtering, thermal evaporation, or pulsed-laser evaporation), chemical vapor deposition (CVD or MOCVD), electroless plating (ELP), electroplating, and diffusion welding (Iniotakis et al. 1987). Each technology has its strengths and weaknesses; therefore, there is a trend of tailoring the deposition technology to the features of the support in order to obtain a suitable composite membrane. The most widely used preparation technology for dense metal layers is ELP due to its ability of covering supports with complex geometries, the simplicity of the required equipment, and its low cost (absence of electrodes or electrical source) (Mallory and Hajdu 1990). On the other hand, PVD magnetron sputtering is a very attractive deposition technology because it could provide thinner uniform

Palladium-Based Membrane (Palladium Alloy Membrane), Fig. 2 Palladium-based commercial tubular membranes manufactured by CRI/Criterion (<http://www.cricatalyst.com/>)

layers (down to only few nanometers), much lower than the thickness achieved with the ELP technique, with a controlled microstructure and composition across of these coatings. Other important advantage of PVD versus ELP is its environmental friendly operation, without producing waste liquids from chemical baths (Klette 2005).

Membrane Commercialization

There are various companies working in the commercialization of palladium-based membranes as reported by Gallucci et al. (2013); Figure 2 shows Pd-based tubular membranes manufactured by CRI/Criterion. As an example of industrial application and membrane scale-up, three commercial membranes from MRT, ECN, and NGK have been used in membrane reactors for methane steam reforming in a pilot plant for 20 m^3/h of hydrogen at Tecnimont KT (Italy) (Palo

et al. 2012); the membranes showed good performance over 1,300 h of testing and 70 cycles of start-up and shutdown with no signs of membrane degradation regarding hydrogen regarding hydrogen permeation properties.

Chemical Engineering and Chemistry, Eindhoven
University of Technology, Eindhoven,
The Netherlands

In palladium-based membrane reactor a hydrogen separation process using palladium-based membranes is coupled with catalytic reactions. It has received a growing interest in recent years (Gallucci et al. 2011; De Falco et al. 2011; Gallucci et al. 2013). Membrane reactors are mainly used to carry out the reactions limited by the equilibrium conversion such as water gas shift (WGS) and so on. In fact, in a membrane reactor the separation capability of a membrane is utilized to improve the performance of a catalytic system.

General Aspects

There are two main generic approaches in Pd-based membrane reactors: selective hydrogen

separation (extractor) and selective hydrogen addition (distributor), as shown in Fig. 1.

The extractor-type membrane reactor facilitates the in situ removal of hydrogen in the case of using palladium membranes. For example, for steam reforming reactions, H₂ yield and CO₂ product selectivity in traditional reactors are limited by thermodynamics. By selective removal of H₂ from the reaction side, the thermodynamic equilibrium restrictions can be overcome following the Le Chatelier's principle. Due to the shift effect, both high H₂ yields and high CO₂ selectivities can be achieved. Besides, this effect allows operation at milder reaction conditions in terms of temperature and pressure (Zaman and Chakma 1994). The distributor-type membrane reactor may use the Pd-based membrane to feed the hydrogen distributively in order to control the contact within reactants. For example, this reactor type can be used for Fischer–Tropsch synthesis reaction (Rohde et al. 2005).

In general, with respect to the traditional reactors, membrane reactors are able to:

- Combine chemical reaction and hydrogen separation in only one system reducing the capital cost
- Enhance the conversion of equilibrium limited reactions

Palladium-Based Membrane Reactor,

Fig. 1 Two approaches in membrane reactors: (a) extractor and (b) distributor (Julbe et al. 2001)

- Achieve higher conversions than traditional reactors operating at the same membrane reactor conditions or the same conditions, but operating at milder conditions
- Improve yield and selectivity

Hydrogen Production by Pd-Based Membrane Reactors

In the late 60s, Prof. Gryaznov proposed the use of Pd-based membrane reactor for dehydrogenation reactions (Gryaznov et al. 1970). Since then, dense Pd-based membranes and microporous silica membranes were studied for hydrogen production by membrane reactors. Pd-based membranes for H_2 production overcome all the other candidate materials due to the very high permeability and infinite perm-selectivity to H_2 . The most commonly studied reactions using Pd membrane reactor have been: methane steam reforming (Chen et al. 2008), methane dry reforming (Gallucci et al. 2008), partial oxidation of methane (Basile and Paturzo 2001; Cheng et al. 2009), and water gas shift reaction (Galuszka et al. 2012). Besides, reforming reactions using other sources were also

studied such as, steam reforming of ethanol and methanol (Gallucci et al. 2007).

Membrane Reactor Configurations

Different types of membrane reactors for hydrogen production have been proposed in the literature. Most of the previous work has been performed in packed-bed membrane reactors (PBMR); however, there is an increasing interest in novel configurations such as fluidized-bed membrane reactors (FBMR) and micromembrane reactors (MMR) especially because better heat management and decreased mass transfer limitations can be obtained in these reactor configurations.

The PBMR configuration is the first and most studied configuration for hydrogen production in membrane reactors. This is because, the first studies on membrane reactors focused on the effect of the hydrogen permeation through membranes on the reaction system. Thus, it was straightforward to compare two packed-bed reactors (avoiding the complication of complex fluid dynamics such as

Palladium-Based Membrane Reactor,
Fig. 2 Packed-bed tubular membrane reactor configurations: (a) catalyst in tube and (b) catalyst in shell (Gallucci et al. 2013)

Palladium-Based Membrane Reactor,

Fig. 3 Schematic representation of a fluidized-bed membrane reactor for selective removal of hydrogen is presented (Adris et al. 1994)

in fluidized bed) in one of which a membrane was used. In a PBMR, the catalyst is confined in fixed-bed configuration and in contact with a Pd-based membrane. The most used PBMR configuration is the tubular one where the catalyst may be placed either in the membrane tube or in the shell side as shown in Fig. 2.

The FBMR configuration consists of a bundle of hydrogen selective membranes immersed in a catalytic bed operated in the bubbling or turbulent regime (see Fig. 3). Compared to PBMR configuration, the use of FBMR reduces the bed-to-wall mass transfer limitations

but also allows operating the reactor at a virtually isothermal condition (due to the movement of catalyst).

The MMR configuration is interesting due to: (i) improved mass and heat transfer owing to the reduction of the scale length in the microchannels; (ii) removal of mass transfer limitations (concentration polarization); and (iii) high degree of process intensification by integrating different process steps in a small-scale device. (Gallucci et al. 2013). The microchannel reactor configuration proposed by Bredesen and coworkers is presented in Fig. 4.

Palladium-Based Membrane Reactor,

Fig. 4 Schematic representation of the microchannel reactor configuration used by Bredeesen for Pd-based membrane tests (Mejdell et al. 2009)

Palladium-Loaded Hollow Fibers: Application in Water Deoxygenation

V. V. Volkov

A.V. Topchiev Institute of Petrochemical Synthesis Russian Academy of Sciences (TIPS RAS), Moscow, Russian Federation

Palladium nanoparticles can be deposited on a hydrophobic porous polypropylene hollow fiber membrane, which preserves its hydrophobic nature (Lebedeva et al. 2006). Prior to the

deposition of palladium onto the membrane surface, hollow fibers should be cleaned with surfactants and organic solvents. Then, their outer surface is etched either by strong inorganic acids or by strong inorganic bases. The next step includes electroless deposition of palladium by one of the two following methods: (1) reduction of palladium tetraaminochloride by hydrazine hydrate (initial membranes are Accurel Q3/2 and Accurel S6/2) and (2) reduction of palladium chloride or palladium acetate by methanol (Accurel Q3/2, Celgard X50) (Volkov et al. 2009). According to the computational analysis of the SEM images, surface porosity of the initial membranes (both Accurel Q3/2 and Celgard X50) slightly increases after pretreatment. All palladium appears to be localized on the outer surface of the hollow fiber membranes. The deposition method (1) is characterized by a high deposition rate, and it provides a nearly dense palladium layer with thickness of 2–3 μm .

The slow wet-chemical deposition method includes the use of aliphatic alcohols (e.g., methanol) which serve as a reducing agent and as a solvent for palladium salts, and this process makes it possible to provide deposition of well-distributed fine palladium nanoparticles. In this case, loading of palladium is well below 20 $\mu\text{g}/\text{cm}^2$, and dimensions of nanoparticles tend to decrease with decreasing level of loading. The EDX and EXAFS observations reveal no other palladium-containing phases (e.g., oxides) and crystallinity of metallic palladium is proved by the XRD analysis. Dimensions of primary particles in their free state and in aggregates are estimated by the methods of X-ray analysis and SEM observations. Dimensions of primary palladium particles range from 10 to 40 nm, and dimensions of their aggregates vary from 200 nm to tens of microns.

Palladium nanoclusters can catalyze DO hydrogenation, thus providing *water deoxygenation by catalytic membranes*, even though the loading of palladium is as low as 5 $\mu\text{g}/\text{cm}^2$. The estimated surface porosity is $(12 \pm 1) \%$, $(17 \pm 2) \%$, and $(17 \pm 3) \%$ for initial Celgard X50, pretreated membrane, and Pd-loaded membrane

(5.4 $\mu\text{g}/\text{cm}^2$ Pd), respectively. For the sample containing $\approx 39 \mu\text{g}/\text{cm}^2$ of Pd, surface porosity cannot be estimated by the computer-aided SEM image processing because the deposited palladium totally occupies the entire structure of porous membranes. Palladium can be deposited either onto individual hollow fiber membranes or onto the surface of membranes within a membrane module. Hence, commercially available membrane module (Liqui-Cel[®]) can be coated integrally as delivered, without any disassembly. Reduction of DO down to its concentration of 10 parts per billion (ppb) and lower is feasible using catalytic membrane reactors based on palladium-loaded porous hollow fibers.

Paper Machine Circulation Water and Membrane Operations

Mari Kallioinen

Lappeenranta University of Technology,
Lappeenranta, Finland

In papermaking great amounts of water are used. First, pulp is diluted with water to form a feasible solution for mixing of the different additives, which improve quality of the produced paper. After that the pulp solution is diluted with water to the consistency, in which it can be spread over the paper machine wire section to form paper. At the wire section, water is removed from the paper web by gravity, low pressure, and pressing the paper web between large rolls. The water collected from the wire section of the papermaking process is called paper mill white water. The circulation of the paper machine white water as such in pulp dilution enables great savings in the amounts of the used freshwater. However, papermaking is still after that a really water-intensive process and the need of freshwater is great. When white water is purified with membranes, it can compensate freshwater and improved water efficiency is achieved. Ultrafiltered white water can be used, for instance, in wire section showers, dilution of chemicals, and in sealing and in lubrication of pumps (Nuortila-Jokinen and Nyström 1996; Nuortila-Jokinen et al. 1999; Huhtamäki 2002).

The internal purification of paper machine white water is attractive, because its volume is one of the greatest of the paper mill effluents. The most significant benefits in water savings can be achieved by treating the streams having the greatest volumes. Clear filtrate, which is paper mill white water clarified by disc filtration or microflotation to recover fiber and to remove most of the suspended solids, can constitute more than half of the total effluent load of a paper mill. To enable the use of clear filtrate at the wire section showers, it has to be free from solids, which could block the shower pipes. Ultrafiltration membranes can produce permeate,

which is free from solids. Moreover, compared to the use of freshwater or flotated clear filtrate, the use of ultrafiltered clear filtrate can reduce slime problems in the shower pipes and potential web breaks or web defects originating from microorganisms and the consumption of biocides, because ultrafiltration removes bacteria and reduces the amount of colloidal bio-organism nutrients. Ultrafiltration reduces also the amount of dissolved and colloidal substances, such as hemicelluloses, starch and resin, and fatty acids, which could cause disturbances in the papermaking process and deteriorate the end-product quality. The use of ultrafiltration can also decrease the consumption of fixatives, because the cationic demand of ultrafiltered process water is significantly lower compared to non-treated process water (Nuortila-Jokinen et al. 1999; Huhtamäki 2002; Huuhilo et al. 2002; Brady 2003; Kreutzman and Sutela 2004; Sutela et al. 2006). When the ultrafiltration permeate is nanofiltered, its COD, conductivity, and anionicity can be significantly reduced, and the nanofiltration permeate can be used as warm freshwater at the mill site.

Ultrafiltration is used to enable the recycling of the clear filtrate at several paper mills. For instance, at UPM-Kymmene Corp. Tervasaari paper mill (Valkeakoski, Finland), CR filters and UF membranes are used to purify 120 m³/h of white water for reuse at wire and press section showers. At SAPPI Ltd Kirjaniemi Paper Mill (Lohja, Finland), 425 m³/h of white water is purified with CR filters and UF membranes for reuse at wire section showers and chemical dilutions (Sutela 2008). At Arctic Paper Munkedal mill (Sweden), tubular UF membranes are used to purify the white water for reuse at wire section showers (Hepp et al. 2005).

Most of the membrane processes at paper mills aim to decrease in fresh water intake, decrease in production of waste waters, and purification of waste waters. Papermaking consumes high volumes of water. In a modern paper mill, the water consumption can be less than 10 m³ water per one ton of produced paper, but in older mills the water consumption can be significantly higher. The use of membrane processes enables the reduction of water consumption to values below 10 m³ per one ton of produced paper.

In efforts to decrease the water consumption of paper mills, the greatest benefits can be achieved by treating and recycling the effluent streams with

the greatest volumes. For instance, ultrafiltration of paper machine clear filtrate (paper machine white water), which can constitute more than half of the total effluent load of a paper mill, enables significant reduction in fresh water use. Ultrafiltration removes suspended solids and microorganisms and reduces the amount of organic dissolved compounds (lignin, hemicellulose, etc.). Ions bound for instance to fibers are also removed. The clear filtrate purified with ultrafiltration can be used at wire section showers, as sealing water, and in dilution of wet end chemicals. Nanofiltration removes, depending on the treated water, conditions and the used membrane from 70 % to 90 % of dissolved organic compounds (COD, TOC), color, and lignin degradation products. In addition, nanofiltration can retain multivalent ions. Nanofiltered paper machine white water can be reused as warm fresh water. The membrane processes treating the paper machine white waters and clear filtrates are operated with high shear rate modules (CR-filter, VSEP-filter), tubular modules, and conventional spiral-wound modules (Linpac 2006; Kreutzman and Sutela 2004; Sutela 2008).

The use of great volumes of water in a manufacturing process leads to the production of great volumes of waste waters. Membrane processes are used also in the treatment of paper mill waste waters to upgrade the purification result of biological waste water treatment and to reduce the amount of scarcely biodegradable compounds in the effluents, which are going to end up to the biological treatment before they are discharged. For instance Eltmann newsprint mill of Papierfabrik Palm has used since 1999 nanofiltration to recycle the effluent from the external biological treatment plant back to the paper mill processes. The concentrate is precipitated with lime to increase its biodegradability and led back to the biological treatment plant (Schirm et al. 2001). Some paper mills have also membrane bioreactors as an essential part of their waste water purification systems (Ramaekers et al. 2001).

In addition to the membrane processes aiming to the decrease of water consumption and environmental load of paper mills, there are also

processes, which aim significant improvements in material efficiency of the mills by recovering valuable compounds from the effluents for reuse at the processes. A great example on a membrane process, which improves material and cost efficiency of the papermaking process and also decreases the environmental load caused by the mill, is ultrafiltration of coating color effluents. Coating effluents form only a small part of the total mill effluents, but they have a strong color and they contain high amount of solids and sticky compounds. Thus, they are not easy to handle in the conventional waste water treatment plant. When the effluent is concentrated with ultrafiltration, the concentrate has a composition close to the original coating color and it can be recycled back to the coating process. When the valuable TiO_2 pigments are used in paper coating, the pay-back time of the ultrafiltration process is typically only around a year. The permeate can be used as sealing water, as washing water, as shower water, as slurry dispersant, or in the dilution of chemicals. The treatment of the coating color effluents is beneficial to do with high shear rate filtration modules (VSEP and CR-filters), because they enable concentration to high dry solid content (even up to 60 %) (Jönsson et al. 1996; Alho et al. 1998; Singh et al. 1999; Lipnizki 2008; Anon. 2013).

Paper Pulp Production and Membrane Operations

Mari Kallioinen
Lappeenranta University of Technology,
Lappeenranta, Finland

A conventional kraft pulp mill can use up to 40 m³ of fresh water to produce 1 ton of chemical pulp (Reeve and Silva 2000). Only about half of the wood is converted to pulp in the pulping process, and the rest of it is dissolved during the process. Thus, great volumes of effluent, which contain

compounds dissolved from wood and chemicals used in pulp-making process, are produced at pulp mills. Nearly half of the water consumed in the pulp mill is used in the pulp bleaching process, and bleaching effluents cause a major part of the color and a significant part of the chemical oxygen demand (COD) load of total pulp mill effluent. They also have high biological oxygen demand (BOD), and, depending on the bleaching chemicals used, they might contain adsorbable organic halogens (AOXs). Efficient purification of the bleaching effluents enables significant decrease in the environmental load caused by the pulp mills.

At pulp mills membrane filtration can be used in treatment of different effluents and process streams to enable water reuse or decrease in environmental load of the mill. The most typical ultrafiltration membrane application at pulp mills is the treatment of alkaline bleaching plant effluents. Ultrafiltration can reduce the color, BOD, COD, and AOX load of bleaching effluents, and it makes it possible to reuse the purified effluent, for example, as washing water. Ultrafiltration prior to the biological treatment also improves the purification result possible to achieve in the biological treatment, because ultrafiltration removes slowly degrading high molar mass lignin compounds and decreases the amount of chlorinated compounds, which are resistant to attack by most microorganisms. The concentrate of the ultrafiltration process is generally burnt in the recovery furnace where the cooking chemicals are recovered. If the mill produces several pulp products, mill effluent quality might vary depending on the products manufactured at the mill. The use of membranes enables high and stable removal of solids, regardless of changes in the effluent quality (Ekengren et al. 1993; Afonso and de Pinho 1995, 1997; Jönsson and Trägårdh 1990; Wallberg et al. 2001).

A real-life example, which is well reported in literature, is the ultrafiltration process used at Stora Enso Nymölla pulp mill (Sweden) which reduces the COD load of the mill effluent prior to its treatment in the activated sludge plant. The UF plant is based on tubular membranes. The total membrane area of the plant is 4,638 m². The ultrafiltration process has enabled

a COD reduction of about 50 % even with high volume reduction factors. The permeate is discharged to an activated sludge plant (Greaves 1999; Nordin and Jönsson 2008; Anon 2013b).

As already mentioned, pulp mill process waters and effluents are rich in compounds dissolved from wood. When the focus of forest industry is moving toward biorefining and toward utilization and also other parts of wood than cellulose, the use of membrane separation at pulp mills most probably increases, because membrane technology enables separation and recovery of the valuable hemicelluloses, lignin, and other compounds from process streams and effluents. There already are good examples, where ultrafiltration is used in recovery of lignin compounds from pulp mill. In Sarpsborg (Norway), at the mill of Borregaard Industries, lignosulfonates have been recovered from spent sulfite liquor for production of vanillin by ultrafiltration since the 1980s (Jönsson and Wimmerstedt 1985; Wagner 2000), and at Domsjö biorefinery (Sweden) lignosulfonates are recovered with ultrafiltration to be used as dispersing agent. At Domsjö mill ultrafiltration is used also in recovery of bioresin from wood (Hildingsson and Domsjö 2014).

Parameter Estimation: Optimization of Membrane Operation

Radoslav Paulen
Department of Biochemical and Chemical
Engineering, Technische Universität Dortmund,
Dortmund, Germany

Parameter estimation, in engineering applications, represents a problem which arises in modeling

and control when one wants to describe physical reality (e.g., behavior of a system) by a model.

Mathematically speaking, it is desired to determine values of model parameters, $\mathbf{p}$, which minimize the difference between the set of n measured data, $\mathbf{y}$, and the set of data, $\hat{\mathbf{y}}$, predicted by a model. This problem can be written as follows:

$$\min_{\mathbf{p}} \sum_{i=1}^n (y_i - \hat{y}_i)^2 \quad (1a)$$

$$\text{s.t. } f(\hat{\mathbf{y}}, \mathbf{p}) = 0 \quad (1b)$$

where Eq. 1b stands for the model, in general a set of equations of different nature (e.g., linear, nonlinear, dynamic, stochastic) which relates predicted behavior of a system with estimated parameters. If $f(\cdot)$ is linear and no other constraints for $\mathbf{p}$ exist, problem (1) has analytical solution. In other cases, one exploits numerical methods such as quadratic or nonlinear programming to solve the problem.

Objective function (1a) represents the so-called least squares estimation cost, and it is recognized in statistics as a maximum likelihood estimation under assumption of normal distribution of measurement error.

Parameter estimation finds its applications in a field of membrane engineering and processes. These include nonlinear estimation of parameters of pervaporation (Cao and Henson 2003), reverse osmosis (Chatterjee et al. 2004), and modeling and control of other membrane processes (Selby and Shannon 2009; Madyastha and Prasad 2011).

Problem of parameter estimation is closely related to finding of intervals of confidence for estimated parameters. In principle, this problem is based on identifying the sensitivities of estimated parameters to observed data and was treated in study of gas permeation in polymers by (Scheichl et al. 2005).

Partial Least Square Regression (PLSR)

René Ruby-Figueroa

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

PLS approach was originated around 1975 by Herman Wold for the modeling of complicated data (Wold et al. 2001). PLS can be defined as a multivariate linear regression methodology, based on the decomposition of the data, into a set of orthogonal components or latent variables (LVs) (Kourti and MacGregor 1995; MacGregor et al. 2005; Metsämuuronena et al. 2002). PLS is recognized as a robust method with a strong statistical basis able to analyze data with noisy, collinear, numerous variables and even missing data points in both the input ($\mathbf{X}$ matrix) and output ($\mathbf{Y}$ matrix) data sets. An important aspect of this technique is that the output data structure guides the decomposition of the input data in a way that the respective orthogonal components explain as much as possible of the

covariance between the input and output (Santos et al. 2007).

As mentioned above, PLS links the input and the output matrices with “new” variables that are estimated as a linear combination of the original variables or their rotation. These new variables called X-scores and denoted by t_a ($a = 1, 2, \dots$, LV) are given by the following equation:

$$t_{ia} = \sum_k W_{ka}^* X_{ik}; (\mathbf{T} = \mathbf{XW}^*) \quad (1)$$

where $\mathbf{W}$ is the weight matrix that relates the X-scores with each variables of $\mathbf{X}$. On the other hand, the input matrix $\mathbf{X}$ can be obtained from the linear combination between the X-scores $\mathbf{T}$ and the loading $\mathbf{P}$ in order to minimize the X-residuals $\mathbf{E}$ (Eq. 2):

$$X_{ik} = \sum_a t_{ia} p_{ak} + e_{ik}; (\mathbf{X} = \mathbf{TP}' + \mathbf{E}) \quad (2)$$

Then, the output matrix $\mathbf{Y}$ can be obtained by means of the following equation:

$$Y_{im} = \sum_a c_{ma} t_{ia} + f_{im}; (\mathbf{Y} = \mathbf{TC}' + \mathbf{F}) \quad (3)$$

where $\mathbf{C}$ is the weight matrix that relates the X-scores with each variable of $\mathbf{Y}$; meanwhile, f_{im} represents the deviation between the observed and modeled responses and comprises the elements of the Y-residual matrix, $\mathbf{F}$.

Finally, the multivariate regression model can be obtained combining Eqs. 1 and 3:

$$\begin{aligned} Y_{im} &= \sum_a c_{ma} \sum_k W_{ka}^* X_{ik} + f_{im} \\ &= \sum_k b_{mk} X_{ik} + f_{im}; (\mathbf{Y} = \mathbf{XW}^* \mathbf{C}' + \mathbf{F} = \mathbf{XB} + \mathbf{F}) \end{aligned} \quad (4)$$

The PLS regression coefficients, b_{mk} ($\mathbf{B}$), can be written as

$$b_{mk} = \sum_a c_{ma} W_{ka}^*; (\mathbf{B} = \mathbf{W}^* \mathbf{C}') \quad (5)$$

The line obtained by linear regression of that swarm of data points, in the direction of maximum

variance, is the first latent variable (LV). In other words, it captures the main trend in the data set. Then, another linear regression is performed in the second direction of maximum variance but keeping in mind that this direction should be orthogonal to the first. This corresponds to the second LV. The remaining LVs are obtained accordingly (Santos et al. 2007).

In any analytical application, data are usually processed before using PLS. Results of projection methods, such as PLS, depend on the scaling of the data. With an appropriate scaling, one can focus the model on more important Y-variables and use experience to increase the weights of more informative X-variables (Erikson et al. 2006). The main techniques to preprocessing data are scaling to unit variance (UV), where the variable is centered and scaled to “unit variance,” and standard normal variate (UNV) that is the same as UV, but the variable is not centered, then the standard deviation is computed around 0.

In any empirical modeling, it is essential to determine the correct complexity of the model. Considering numerous and correlated X-variables, a substantial risk exists for “over-fitting” that means a well-fitting model with little predictive power (Wold et al. 2001). Cross-validation (CV) is a practical and reliable way to test the predictive significance (Höskuldsson 1996). Basically, in CV, the data are divided in groups followed by the development of parallel models that are evaluated with the differences between observed and predicted Y-values. In the evaluation, the observations are kept out of the developed model, while the response values (Y) are predicted and compared with the observed values. The procedure is repeated several times until every observation has been kept out. The sum of squares of these differences is computed and collected from all the parallel models to form the predictive residual sum of squares (PRESS), which estimates the predictive ability of the model (Wold et al. 2001). Finally, the model with the number of components giving the lowest PRESS is used. The ability of the model can be summarized using the R^2 that is the fraction of the sum of squares (SS) of Ys explained by the current

component and Q^2 (cross-validated R^2) which is the fraction of the total variation of the Ys that can be predicted by a component. The selected model needs to be validated before using it to understand or to predict new events. The best validation involves the use of new X-values also known as validation set, but an independent and representative validation is rare (Wold et al. 2001). In the absence of a real validation set, the best solution is to use a cross-validation approach which simulates how the model predicts new data well and model reestimation after data randomization which estimates the chance (probability to get a good fit with random response data).

The PLS applications have been reported in three principal areas: quantitative structure-activity relationship (QSAR) modeling, multivariate calibration, and process monitoring and optimization (Wold et al. 2001). This approach can be applied in membrane processes in order to correlate operating conditions as well as membrane characteristics (X matrix) with several response variables (Y matrix) such as permeate flux, selectivity, etc.

Partial Pressure Profile

Alessio Caravella

National Institute of Advanced Industrial Science and Technology – Research Institute for Innovation in Sustainable Chemistry, ISC-AIST, Tsukuba, Ibaraki, Japan

In the field of *Membrane Technology*, the partial pressure profiles mostly refer to pressure profiles of a key species of interest established within a membrane device and/or through the membrane itself.

Concerning the partial pressure profile within membrane devices, they can be evaluated by numerical techniques like, as an instance of the most common one, computational fluid-dynamics simulation, implementing the momentum, energy, and mass conservation equations over the domain of interest together with the specific boundary conditions, which are usually defined at the

membrane surface in terms of known flux and/or concentration of the species involved in the process.

As for the partial pressure profile in membrane, they are usually determined by solving complex permeation models including several elementary transport mechanisms. Both complexity and type of the considered permeation model determine the shape of the specific transmembrane partial pressure profiles.

As instances of permeation models commonly used for dense and porous membranes, the profiles of chemical potential and pressure (for just one permeation species equivalent to the partial pressure) relative to the *solution-diffusion* model and the *pore-flow* model are sketched in Figs. 1 and 2 (Wijmans and Baker 1995).

Strictly speaking, since a pressure can be only defined for a fluid phase, partial pressure profiles can be basically established in porous membranes only, as the state of the permeating species inside dense membranes is actually an adsorbed/dissolved state.

Partial Pressure Profile,

Fig. 1 Profiles of pressure, chemical potential, and solvent (membrane) activity according to the solution-diffusion model (Reprinted from Wijmans and Baker (1995) with the permission of Elsevier Science B.V. 1995)

Partial Pressure Profile,

Fig. 2 Profiles of pressure, chemical potential, and solvent (membrane) activity according to the pore-flow model (Reprinted from Wijmans and Baker (1995) with the permission of Elsevier Science B.V. 1995)

Nevertheless, it is also possible to represent the concentration profiles in dense membranes by the so-called equivalent partial pressure, which is the partial pressure of the permeating species being in equilibrium with its actual concentration in membrane at every position between the membrane surfaces on feed and permeate side (see, e.g., Caravella et al. 2008).

Pd-Alloy Membrane Preparation Techniques

Thijs Peters

SINTEF Materials and Chemistry, SINTEF, Oslo, Norway

Current Pd-alloy membrane technology comprises self-supported and mechanically supported composite structures. Self-supported membranes are usually in the form tubes or foils with thickness range of 50–100 μm with thicker membranes used at higher total transmembrane pressure. The H_2 flux, being in most cases inversely proportional to the thickness of the membranes, is too low for most applications to give a favorable cost-performance combination for most applications, apart from for small-scale H_2 production in the electronics industry. For broader use it is therefore necessary to develop membranes with a reduced thickness of the Pd layer, and for economically viable membranes a five to tenfold reduction in thickness is necessary. Research in recent years has therefore focused on the development of composite membranes consisting of a thin Pd-based separation layer on a mechanically strong support. The typical state-of-the-art composite Pd-alloy

membrane consists of a Pd separation layer of 2–10 μm thickness on a ceramic or metallic support.

Numerous reports exist describing different methods to fabricate such composite membranes. The most common are electroless plating, electroplating, CVD, sputtering, and various particle deposition techniques. Generally, for these methods, the thin Pd or Pd-alloy layer is prepared directly on the surface or inside the pores of the support. A lower thickness limit apparently exists, however, for which a dense and pinhole-free layer can be obtained during the direct deposition on a support. This thickness limit increases with increasing surface roughness and pore size in the support's top layer. Methods to circumvent support quality problems are developed and include support filling prior to plating, simply closing defects present after membrane manufacturing by selective deposition of Pd within them, or to manufacture the Pd selective layer independently of the support. In the latter process, a defect-free Pd-alloy membrane is first prepared by sputtering deposition onto the “perfect surface” of, e.g., a silicon wafer. In a second step, the membrane is removed from the wafer and transferred to a porous stainless steel support. This allows the preparation of very thin ($\sim 1\text{--}2\ \mu\text{m}$) defect-free membranes supported on macroporous substrates (pore size equals $\sim 2\ \mu\text{m}$).

The most frequently applied membrane manufacturing technique, electroless plating, has low cost and is applicable for large-scale production, but becomes increasingly more complex with the number of alloying elements. This is an important limitation in the membrane production as more advanced ternary or quaternary alloys may be needed to improve performance and stability (see “► [Ternary Pd-Alloy Membranes](#)”). Magnetron sputtering enables production of complex alloys with controlled stoichiometry in a controlled manner. In principle, the composition of the prepared film is homogeneous in the composition of the target applied, preventing thus the high temperatures required for alloying (550 $^\circ\text{C}$) that can be detrimental to the membrane integrity. However, magnetron sputtering is currently less developed for large-scale membrane production.

Pd-Based Composite Membranes

Yan Huang

State Key Laboratory of Materials-Oriented Chemical Engineering, College of Chemical Engineering, Nanjing Tech University, Nanjing, China

Pd-based composite membrane (also called supported membrane). Pd-based membranes include pure palladium and palladium alloy membranes. They are highly permeable and almost 100 % permselective toward hydrogen (including its isotopes, i.e., deuterium and tritium). All gases and steams except for hydrogen will be rejected, yielding ultrapure hydrogen. The palladium-based membranes have been commercialized since 1960s, when Pd-Ag membranes were developed by Johnson-Matthey Co. and applied in hydrogen purification. They are often in forms of either tubes or foils and can be manufactured by cold drawing or rolling. For example, the cold rolling can be operated by (i) preparing a palladium alloy with certain composition by melting at high temperature, (ii) ingot casting, (iii) high-temperature homogenizing, (iv) hot and cold forging or pressing, and (v) repeated cold rolling and annealing (Shu et al. 1991). The membrane thickness is usually several tens of microns.

Because of the disadvantages of the conventional palladium-based membranes such as poor physical strength and high cost, a concept of composite or supported membrane was introduced, which comprises a thin layer of palladium or palladium alloy and a porous substrate. At first, the mechanical strength of the membrane can be greatly enhanced by the substrate. Secondly, the membrane thickness can be significantly reduced down to several microns, and the membrane permeance will accordingly increase because the membrane permeance is inversely proportional to the membrane thickness. Thirdly, the palladium consumption and the membrane cost can be greatly reduced because of the

reduction in membrane thickness as well as the decrease in the necessary membrane area.

However, the disadvantages of the composite membrane concept remain. It is difficult to avoid the membrane defects during membrane fabrication, and the maintenance of the membrane stability is also challenging because pinholes may appear along with the time on stream.

A photograph of various palladium-based composite membranes is exhibited in Fig. 1, and some Pd/Al₂O₃ membranes with a length of 1.2 m and a diameter of 13 mm are shown in Fig. 2.

Substrate Material

Due to their excellent chemical stability and broad market availability, porous ceramics and stainless steels are the most popular substrate materials for the composite palladium-based membranes. Principally, the porous ceramics have better surface properties and facilitate the membrane fabrication, but they are fragile and may lead to problems in membrane module construction. On the contrary, porous stainless steels can be welded and easy to connect with other metallic parts, whereas their pore size is often too large. Moreover, direct use of the porous stainless steels as substrate material of the palladium-based membranes will cause intermetallic diffusion problems. A ceramic coating on the porous stainless steels will not only improve the surface properties but also act as a barrier (Huang and Dittmeyer 2006). Since the defects such as big cracks and holes at the substrate surface may eventually lead to the defects in the membrane, it is important to test the surface pore size of the substrate before use, and for this purpose a capillary flow or bubble point method can be conveniently applied (Yu et al. 2010).

Membrane Preparation

Most of the commercialized self-support palladium-based membranes are made of palladium alloys such as Pd77Ag23, Pd60Cu40, Pd92Y8, etc. On one hand, pure palladium membranes suffer from hydrogen embrittlement

Pd-Based Composite Membranes,

Fig. 1 Photograph of various palladium-based composite membranes (http://www.njgaoq.com/products_detail/&productId=68.html)

Pd-Based Composite Membranes,

Fig. 2 Scale-up of the palladium-based composite membranes by GaoQ Functional Materials Co., Nanjing, China. (http://www.njgaoq.com/products_detail/&productId=70.html)

problem. On the other hand, the introduction of the other metals may improve the membrane permeability, physical strength, and/or poison resistance. In the case of the type of the composite membranes, the fabrication of the palladium alloy membranes is more difficult because of the difficulty in direct deposition of thin and defect-free palladium alloy layer on the porous substrate surface. Therefore, the palladium and the other metal(s) have to be deposited either sequentially or simultaneously, followed by a heat treatment for the formation of homogeneous palladium alloy. In general, the sequential deposition is the most common, and palladium is deposited at first.

Although there are many techniques that can be used in metal coating and deposition, such as

electroplating, chemical vapor deposition (CVD), magnetron sputtering, plasma thermal spray, and high velocity oxy-fuel (HVOF) spray, the electroless plating is almost the best as far as the deposition of palladium is concerned. Before plating, the substrate surface is often activated by a $\text{SnCl}_2/\text{PdCl}_2$ treatment to seed a layer of palladium nuclei as a catalyst. The palladium plating bath is often composed of PdCl_2 , Na_2EDTA , $\text{NH}_3\text{H}_2\text{O}$, and N_2H_4 , and the reaction during electroless plating is

During alloying of palladium and the other metal(s), a very high temperature (e.g.,

600–900 °C) and a long heating time are often necessary. However, such a severe heat treatment for such a thin metal layer may cause significant membrane defects and consequent poor membrane selectivity. Therefore, the composite membranes of pure palladium are still a good choice. In order to avoid the hydrogen embrittlement problem, the operating temperature of the pure palladium membranes should be above 300 °C, and below this temperature the raw hydrogen gas should not be fed to the membranes. After operation, the membrane should be purged with inert gas or vacuumed before cooling down. At a temperature below 300 °C, whether the hydrogen embrittlement occurs or not will depend on the partial pressure of hydrogen. For example, palladium will not be embrittled at 160 °C if the H₂ pressure is below ca. 2 bar, but above this pressure the H/Pd ratio will rapidly increase because of the formation of β -type palladium hydride, leading to a sudden expansion and a strong tension in palladium lattice (i.e., the so-called hydrogen embrittlement). To protect the composite membranes for longer operation life, rapid changes in hydrogen pressure and working temperature should be avoided anyhow.

Application

The applications of the palladium-based-composed membranes are almost the same as those of the conventional self-stand ones. Apart from the applications in hydrogen separation, purification, and recycling, they can be also used as membrane reactors for hydrogen-related reactions such as hydrogen production, hydrogenation, and dehydrogenation. In addition, they can be used even as membrane catalysts (Shu et al. 2009; Shi et al. 2010).

Pd-Based Membrane: Exposure to Coal Gas

Thijs Peters

SINTEF Materials and Chemistry, SINTEF, Oslo, Norway

Pd-based membranes have frequently been studied in membrane reactors for steam reforming (SR-MR) and water-gas shift (WGS-MR) reactions to simultaneously achieve a high methane conversion and production of pure H₂. A key feature of this process intensification is that such a membrane reactor would produce both a high-pressure CO₂ stream and high-purity H₂. Synthesis gas may also be produced by gasification of coal or biomass, enabling production of hydrogen from these important sources. Downstream processing of gasification effluents, i.e., separation or further reaction, is however more challenging than in the case of natural gas because of the wide range of possible impurities and by-products associated with the coal or biomass. Coal-derived synthesis gas can contain up to 15,000 ppm H₂S as well as COS (<0.1 %), NH₃ + HCN (<0.3 %), C₂ hydrocarbons, polyaromatic hydrocarbons (PAHs), halides (such as CH₃F, CH₃Cl at around 2 ppmv), heavy metals (such as Hg, Cd, Pb), tellurides (arsenides, selenium, antimony), alkali metals (Na, K, Ca), phosphorous, tars, and other unknown compounds, in concentrations varying with the source of the feedstock and the

gasification technology applied. Even though some field tests applying Pd-based membranes in actual coal-derived syngas have been performed, the reactivity of the majority of these compounds with Pd and its alloys is not known.

With current understanding, production of hydrogen from coal and other sulfur-containing sources is challenging for Pd-based membranes particularly due to their limited stability toward sulfur. Even a few ppm of sulfur in the gas reduces the flux drastically due to strong surface adsorption leading to reduced permeability, while higher concentrations (typically above 100 ppm depending on operating temperature) even lead to a complete deterioration of the membrane caused by formation of bulk Pd₄S. This has led to the development of a number of new alloys with higher sulfur tolerance (see entry “► [Ternary Pd-Alloy Membranes](#)”). Still, however, flux targets remain a challenge for these alloys in large-scale applications in the presence of sulfur impurities. For application of Pd-alloy membranes in coal-derived synthesis gas, sulfur needs thus to be removed by processes such as ZnO beds and hydrodesulfurization. This desulfurized synthesis gas may still contain trace levels of H₂S, and it is therefore important to assess the stability of Pd-alloy membranes under long-term exposure to trace levels of H₂S and to determine the upper acceptable H₂S level.

Pd-Based Membrane: Scale-Up

Thijs Peters

SINTEF Materials and Chemistry, SINTEF, Oslo, Norway

Pd-based membrane technology is currently the standard for small-scale H₂ production (~0.25–150 Nm³/h) in the electronics industry as they can provide hydrogen to nine-nines purity, meeting the most stringent requirements for semiconductor fabrication processes. The technological standard for the production of ultrahigh purity

hydrogen is based on self-supported rolled foils or drawn tubes with thickness range of 50–100 μm. To increase cost-effectiveness compared to alternative technologies and processes, driven by the prospected use of hydrogen as an energy carrier, composite membranes with a reduced thickness of the Pd layer on a mechanically strong support are being developed. Here, the most frequently applied membrane-manufacturing technique, electroless plating, has low cost and is applicable for large-scale production; see Pd alloy membrane preparation techniques. Along this route, tubular composite membranes on porous metal supports have been developed by several companies, like Shell/CRI-Criterion, Pall Corporation, and Plansee/Linde for application in membrane-intensified steam reformer concepts. CRI Criterion currently produces membranes of ODs up to 2 in. and lengths up to 24 in. In addition, tubular membranes on ceramic support for application in WGS membrane reactors are offered on a pre-commercial basis by ECN/Hysep[®]. These modules, currently with membrane area up to 0.5 m², are only suitable for hydrogen separation. The nominal capacity of the largest membrane module equals 3.5–6 Nm³·h⁻¹, based on the obtained hydrogen flux applying reformat with 33 % H₂, an inlet pressure of 25 bar and H₂ outlet pressure of 4 bar.

For successful commercialization of Pd-based membranes, the membrane must have sufficient permeability, selectivity, robustness, and durability in relevant environments. Therefore, many companies and research institutes are as well working on pilot projects to demonstrate the technical feasibility of the Pd membrane technology. Although this effort is still mainly limited to laboratory-scale membranes or modules, some new (pre)commercial membrane modules have been successfully applied in pilot plant and industrial facilities. Tokyo Gas uses plate-type membranes incorporating Pd-based foils supported on stainless steel carriers in their 40 Nm³/h-class membrane reformer, and a membrane reforming pilot plant with 20 Nm³/h of hydrogen capacity has been constructed by Kinetics Technology in Italy to investigate different types of Pd-based membranes.

Pd-Based Tubular Membrane Reactor

Giuseppe Barbieri

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

A *Pd-based tubular membrane reactor* consists of two concentric tubes where the internal one is the metallic membrane separating the two reactor sides, that is, the reaction and permeate volumes. The reaction side can be the core of the inner tube or the annular volume between the two tubes. The Pd-based membranes are used since they are permeable only to hydrogen. Therefore, such a reactor will be mainly evaluated on two performance parameters: feed conversion and hydrogen recovery on permeate side.

A reactor having a prevalent geometrical development along a specific direction is known as tubular reactor. Its most common cross section is the circular one even though other sections such as square, rectangular, etc., are possible. Thus, a cylindrical surface mostly delimits such a reactor and two circles define the entrance and exit surfaces.

Such a tubular reactor with a circular cross section is commonly used both industrially and at a lab scale. This configuration allows the pressure on the reactor surface to be uniformly distributed, a very important issue for industrial application where the pressure can be really high; in some cases (see ammonia synthesis), the reaction pressure reaches 600–1000 bar. This reactor is commonly used in the laboratory for its cylindrical symmetry which allows to reducing the complexity of the equation set for mass and energy balance. Often, in a first approximation, radial and axial diffusions of mass and energy are neglected, and the resulting mathematical model consists in an ODE (ordinary differential equation) system of the first order whose resolution is much simpler than that of PDE (partial differential equations) system of the second order necessary for the mathematical description in the absence of cylindrical symmetry and radial and axial

diffusions. This reactor model, known as plug flow reactor (PFR), is the most common experimental investigated since its mathematical description consisting in a first-order ODE set, as above said, is the simplest one from a fluidodynamics point of view after the continuous stirred tank reactor.

The reactor diameter ranges from a few centimeters to meters also depending on the exothermicity/endothermicity of the reaction, in other words on the necessity of heat exchange/provision. Often, industrial reactors operate in adiabatic conditions, but in some cases the heat request by reaction is so high that energy has to be provided in order for the reaction to precede; in these cases small diameter is preferred to the higher one.

The simplest *Pd-based tubular membrane reactor* utilized the various advantages (cylindrical symmetry, no radial and axial diffusions) of a plug flow reactor on reaction side; this condition is also valid for the permeate volume. This membrane reactor (MR) model is mathematically described by a first-order ODE set. The two streams in the reaction and permeate volumes can be in co- or, as shown in the next figure, countercurrent configurations. The permeation driving force, the difference between the square root of hydrogen partial pressure on reaction and permeation sides, of a co-current tubular MR is the highest at the entrance and it reduces along the reactor length; if the reactor is really long, this difference becomes null. The permeation driving force of a countercurrent tubular MR is more distributed along the reactor length (Barbieri and Di Maio 1997). Therefore, countercurrent flow configuration results in a higher performance in terms of, e.g., reaction conversion and hydrogen recovery. The countercurrent configuration requires a shooting method for the numerical solution of the ODEs set. Equation 1 shows an example of an ODE system for an MR operating in steady state (Fig. 1):

$$\begin{aligned}
 -\frac{dF_i}{dz} + [\text{Generation by reaction}] \\
 - [\text{Permeation through the membrane}] \\
 = 0
 \end{aligned} \tag{1}$$

Pd-Based Tubular Membrane Reactor, Fig. 1 Scheme of Pd-based membrane reactor

The choice about the reaction volume as the one inside the core of the membrane or in the annular space between the two tubes depends on several factors, e.g., contact between the catalyst and membrane (can damage the membrane since this is a few microns thin) and heat transfer from the energy source and reaction. The heat transfer is more efficient (Marigliano et al. 2001) if the reaction takes place in the annular space since the resistance in this case is concentrated in the external tube and in the gas films around it. In the other case, the overall heat transfer coefficient is lower since the energy has to be transported through the permeation volume too.

Different reactor configurations and geometries also including radial and axial diffusions are often operated also at lab scale for analyzing the effect related to the mass and energy diffusive transport. The following Eq. 2 shows the complexity of PDE set of a two-dimensional second-order mathematical model written down for a tubular MR operating in steady state:

$$\begin{aligned} & \text{Diffusivity}_{i,z} \frac{\partial^2 p_i^{\text{ReactionSide}}}{\partial z^2} \\ & + \text{Diffusivity}_{i,r} \frac{\partial^2 p_i^{\text{ReactionSide}}}{\partial r^2} + R_{\text{gas}} T_{r,z}^{\text{ReactionSide}} \\ & \left(\frac{\partial N_{i,z}^{\text{ReactionSide}}}{\partial z} + [\text{Generation by reaction}]_{r,z} \right) = 0 \end{aligned} \quad (2)$$

Models for more complex reactor configurations and geometries also including radial and axial diffusions are reported in (Barbieri et al. 2008a) and characterized by first- and second-order PDE set.

Two more aspects have to be discussed for an MR: the concentration gradients, more known as concentration polarization, and the permeation reduction owing to the presence of some gases since both reduce the membrane performance.

The permeation is a mass transport happening at a surface – the one delimited by the membrane – and when it is selective creates a variation in the composition of species in the film close to the membrane itself. This variation will spread with a finite – not infinite – velocity; this means a concentration profile is created in the orthogonal direction at the membrane surface. The concentration profile is physiological in any membrane separation and its breadth depends on membrane selectivity and permeance. The higher the selectivity and permeance, the higher the concentration profile (Caravella et al. 2008, 2009; Boeltken et al. 2013). The presence of a concentration gradient reduces significantly the driving force for the permeation, that is, function of the partial pressure at the membrane surface and not the one in the bulk of the reaction and permeation phases.

The adsorption of some species such as CO and H₂S (Gade et al. 2011; Morreale et al. 2004; Kulprathipanja et al. 2005; Braun et al. 2012; Kajiwarra et al. 1999; Gabitto and Tsouris 2009; Chen and Ma 2010; Iyoha et al. 2007) on the membrane surface causing the reduction in the number of metal surface sites for hydrogen adsorption is a fundamental step for hydrogen permeation. This phenomenon, known in catalysis as poisoning of catalysts, follows the same adsorption laws, e.g., the Langmuir one (Barbieri et al. 2008b). It results in a significant increase of permeation resistance and similar

permeance reduction (Caravella et al. 2010). Both concentration gradients and inhibition by chemical species have to be taken into account for a proper evaluation of hydrogen permeation (Caravella et al. 2010, 2011; Barbieri et al. 2011) and hence membrane reactors performance.

Pd–Cu Alloys for Hydrogen Separations

Kew-Ho Lee

Center for Membranes, Korea Research Institute of Chemical Technology (KRICT), Yuseong-gu, Daejeon, South Korea

Pd–Cu alloys have been widely studied as a hydrogen separation membrane because they do not show embrittlement even at low temperatures (Kulprathipanja et al. 2005; Miller et al. 2008). Studies by Morreale et al. have shown that the face-centered cubic (fcc) phase is more resistant to sulfur than the body-centered cubic (bcc) phase

(Morreale et al. 2004). In transient experiments, the fcc Pd–Cu composition showed a decline of 0–10 % when exposed to 1,000 ppm of sulfur, while a bcc Pd–Cu composition had a decline of 99 %. Studies by Pomerantz and Ma (Pomerantz and Ma 2009) confirm these results for Pd–Cu compositions of 8, 18, and 19 wt.% Cu, with permeance losses of 80 % at 500 °C (773 K). They further showed that the loss was partially reversible by hydrogen treatment. A recent study by Howard and coworkers (O'Brien et al. 2010) shows that Pd exposed to 1,000 ppm sulfur at 350 °C (623 K) corrodes over a period of hours to form a thick (6.6 μm) PdS₄ layer, probably by an autocatalytic process. In contrast a Pd₄₇Cu₅₃ alloy forms a thin (~ 3 nm) Pd–Cu–S layer. Although this layer cannot dissociate hydrogen or is impermeable to hydrogen, it does protect the bulk from sulfidation and could be removed by a hydrogen treatment.

The alloying of Cu with Pd increases the resistance for the α to β phase transition in Pd–H system. Moreover the phase transition in the Pd–H system is eliminated even at room temperature by adding more than 8 wt.% Cu in Pd (Karpova and Tverdokskii 1959). McKinley (McKinley et al. 1969) studied the permeation characteristics of Pd–Cu alloys with different compositions. The H₂ permeabilities of various alloys are shown in Table 1. Out of all other Pd–Cu alloys, the Pd₆₀Cu₄₀ shows the highest permeability which corresponds to the ordered β -phase in Pd–Cu system (McKinley and US. Patent 3, 439, 474 1969). In contrast, it is reported that Pd₄₇Cu₅₃ (mol%) alloy has the highest hydrogen permeability at 350 °C among

the Pd–Cu alloys (Yuan et al. 2007; Yang et al. 2007; McKinley et al. 1969; Roa et al. 2002) and is comparable in its hydrogen permeability to pure Pd at the same temperature. The solubility of Pd–Cu (20 % Cu) is five times smaller than that of pure Pd, which corresponds to the permeability behavior of that alloy (Sonwane et al. 2006).

In summary Pd–Cu (particularly Pd₆₀Cu₄₀) is the most promising composition; has the characteristics of having high hydrogen permeance, good sulfur resistance, robustness w.r.t. thermal cycling, and an excellent dimensional stability (small degree of swelling); is cheaper; eliminates warping and cracking; and avoids α to β phase transition in pure Pd (Gabbito and Tsouris 2009).

Pectin Hydrolysis and Membrane Operations

Katalin Belafi-Bako

Research Institute of Bioengineering, Membrane Technology and Energetics, University of Pannonia, Veszprem, Hungary

Hydrolysis of pectin can be carried out by pectinase enzymes that are classified into three main groups (Pilnik and Voragen 1993):

- Pectinesterases – catalyzing de-esterification of the methoxyl group of pectin
- Depolymerizing hydrolytic enzymes (including polymethyl-galacturonases and polygalacturonases) – catalyzing the hydrolytic cleavage of 1,4-glycosidic bonds
- Lyases – catalyzing the cleavage of glycosidic bond by transesterification

Among the pectin hydrolyzing enzymes, (endo)polygalacturonases (PG, E.C. 3.2.1.15.) play a key role in the process. Regarding the kinetics it was found that PG enzyme from *Aspergillus niger* was inhibited by its monomeric product, galacturonic acid. The Michaelis-Menten model completed with competitive product inhibition describes properly the process.

To avoid product inhibition in hydrolysis of pectin, the inhibiting product should be removed by, e.g., a membrane separation. Ultrafiltration membranes provide proper separation since the small inhibitory product molecule (galacturonic acid) can easily pass through the membrane and be removed continuously from the system, while the large molecules (substrate and enzyme) are retained by the membrane. The enzymatic

reaction and the membrane separation can be carried out simultaneously in the same setup, which is called membrane bioreactor (Belafi-Bako et al. 2007; Kiss et al. 2009). In this way higher yields and efficiency can be achieved.

Pectolytic enzymes have been used for long in the fruit processing industry to increase yields, to improve liquefaction and clarification (Pilnik and Voragen 1993), and moreover to produce D-galacturonic acid (monomer of pectin), which is an important compound, raw material in the food, pharmaceutical, and cosmetic industry to manufacture, e.g., vitamin C or acidifying, tensioactive agents.

Pectins

Katalin Belafi-Bako

Research Institute on Bioengineering, Membrane Technology and Energetics, University of Pannonia, Veszprem, Hungary

Pectin is a general term for various polysaccharides. According to a standard nomenclature (Nelson et al. 1977), pectic substances are a group of complex, colloid carbohydrate polymers which are present and recovered from plant tissues and consist of mainly galacturonic acid as monomer (Walter 1991). Regarding structure, three different pectic polysaccharides can be

distinguished: homogalacturonan (HGA) and rhamnogalacturonans I and II (RGs I and II).

HGA is a linear polymer consisting of D-galacturonic acid monomers. The backbone of RG I is built from rhamnose and galacturonic acid alternately, while the main bone of RG II is composed of linear oligogalacturonic acid sequences (eight to ten monomers), where various monosaccharides are coupled to, resulting in a complex, branching polymer. The galacturonic acid units may occur in a free acid form, esterified by methanol, or as a salt formed with Na^+ , K^+ , and NH_4^+ ; moreover it may contain acetyl groups coupled to the OH groups. The composition of pectins (galacturonic acid content, molecular weight, methylation, acylation degree, etc.) depends on the source, i.e., pectins from citrus fruits have low esterification degree.

Pectin is widely used as thickening, gelling, and emulsifying additive in food, cosmetic, and pharmaceutical industries (Walter 1991).

and separation (clarification, purification, and concentration). In the separation steps, membrane processes (mainly ultrafiltration) can be widely applied.

In the commercial pectin extraction process, citrus peels and apple pomace are used as raw materials. However pectin recovery from agro-wastes would be more beneficial, since it is not only important from the environmental protection point of view (waste minimalization), but it may contribute to the more economical production. The potential pectin-rich agro-wastes are, e.g. cocoa husks, sunflower head, peach pomace, peels of mango, etc. Recently wastes of berry fruit (red and black current, blackberry, elderberry, etc.) processing have been studied (Belafi-Bako et al. 2012).

Extraction of pectic substances can be carried out by hot aqueous (acidic or neutral) solution in high temperature. It takes quite long (appr. 10–12 h). To improve the process, microwave technique can be applied (Fishmann et al. 2006).

As a result of the extraction (from, e.g., the berry press cakes by boiling water), majority of the pectic polysaccharides can be obtained in the aqueous phase. *Ultrafiltration* can be used then to clarify the extracted solution, and the diluted aqueous pectin solution may be concentrated partly by membranes (e.g., *ultrafiltration*, or *nanofiltration*, or *reverse osmosis*) up to 5 % total solid substance (TSS), partly by evaporation up to 30 % TSS. Then pectin in powder form can be obtained from the concentrated pectic solution after precipitation with ethyl alcohol.

PEGylation

Andrew L. Zydney

Department of Chemical Engineering, The
Pennsylvania State University, University Park,
PA, USA

PEGylation refers to the covalent attachment of one or more polyethylene glycol (PEG) chains to another molecule, typically a small therapeutic protein (Veronese and Harris 2002). The attachment of the PEG increases the hydrodynamic size of the protein, reducing the clearance by the kidney and significantly increasing the half-life of the protein thereby reducing the dosage level and frequency. PEGylation can also reduce the antigenicity of the protein, significantly reducing any adverse immune response (Veronese 2009). A variety of commercial PEGylated proteins are currently on the market (Table 1).

PEGylation is typically accomplished by reacting an activated form of the polyethylene glycol with available reactive groups on the surface of the therapeutic molecule. This includes the free amino groups on the amino acid lysine as well as the free sulfhydryl group on the amino acid cysteine. The N-terminal amino group and the C-terminal carboxylic acid can also be used for site-specific PEGylation.

One of the challenges in producing PEGylated therapeutics is the need to remove the unreacted protein and PEG, as well as any multiply PEGylated species, from the desired (typically singly) PEGylated product (Fee and Van Alstine 2006). A variety of chromatographic methods have been developed for the purification of PEGylated proteins including size exclusion chromatography, ion exchange chromatography, and hydrophobic interaction chromatography (Fee 2009).

There is also considerable interest in the development of ultrafiltration systems for the purification of PEGylated proteins. Molek and Zydney (2007) demonstrated the use of ultrafiltration to remove the unreacted protein, reaction by-products, and unreacted PEG from a desired PEGylated protein using a two-stage diafiltration process. The first stage used an electrically neutral membrane to remove the small unreacted protein, with the neutral PEG removed in a second stage using an electrically charged membrane that provided high retention of the charged PEGylated protein. Ruanjaikaen and Zydney (2011) used a charged ultrafiltration membrane to remove multiply PEGylated species from singly PEGylated α -lactalbumin, with the more heavily PEGylated species retained by the charged ultrafiltration membrane using a combination of size and electrostatic interactions.

PEGylation, Table 1 Examples of commercial PEGylated products

Commercial name	Protein	Manufacturer	Indication
Adagen	Bovine adenosine deaminase	Enzon	Severe combined immunodeficiency
Oncaspar	L-asparaginase	Enzon	Acute lymphoblastic leukemia
PegIntron	Interferon alpha-2b	Schering-Plough	Hepatitis C, hepatitis B
Neulasta	Granulocyte colony-stimulating factor	Amgen	Neutropenia
Pegasys	Interferon alpha-2a	Hoffman-LaRoche	Hepatitis C, hepatitis B
Somavert	Modified human growth hormone	Pharmacia-Upjohn	Acromegaly
Macugen	Pegaptanib sodium	Osi Pharmaceuticals	Wet macular degeneration
Cimzia	Monoclonal antibody (TNF-alpha blocker)	UCB, Inc.	Crohn's disease, rheumatoid arthritis
Pegloticase	Uricase	Savient	Chronic gout

Perfluoropolymers PFP

Perfluoropolymers are fluorocarbon-based polymers with multiple carbon-fluorine bonds. This unique class of polymers has been widely used in membrane technology for their excellent

chemical and thermal stability, high mechanical strength, and versatile processability. The main application areas of fluoropolymer membranes have been focused on microfiltration (MF), ultrafiltration (UF), and battery separators. Recently, however, the application ranges are expanding into new innovative applications like membrane bioreactor (MBR), membrane distillation (MD), membrane crystallization (MCR), and pervaporation.

Since each application calls for different membrane performances, membranes need to be tailored using appropriate materials and fabrication methods. Some of the key fluoropolymers used to prepare membranes are summarized in Table 1.

PVDF is by far the most widely used fluoropolymer to prepare membranes. Although chemically inert (nonreactive), it has high solubility in polar aprotic solvents, allowing PVDF membranes to be fabricated via the nonsolvent-induced phase separation (NIPS) method. PVDF is also a semicrystalline and thermoplastic polymer with a relatively low melting point around 170 °C, allowing it to be melt processed into different morphologies. In addition, with appropriate solvents, highly porous and uniform PVDF membranes can be prepared via the thermally induced phase separation (TIPS) method. As most fluoropolymers are intrinsically hydrophobic (i.e., low surface energy), fluoropolymeric membranes for water treatment applications are typically post-treated using different hydrophilization methods. In addition, depending on the fabrication method and protocol, PVDF can assume different crystal morphologies (α -, β -, and γ -phases) where β -phase can yield antifouling effects.

ECTFE is a semicrystalline copolymer of ethylene and chlorotrifluoroethylene with excellent chemical resistance to corrosion and solvent degradation. Compared to the PVDF polymer, processing ECTFE into membranes is slightly more cumbersome as it does not dissolve in any known solvent at ambient temperature. However, with appropriate solvents at high temperatures (150–250 °C), ECTFE membranes can be fabricated via the TIPS method. The excellent thermal

Perfluoropolymers in Membranes, Table 1 Main perfluoropolymers used to prepare membranes (Cui et al. 2014)

Polymer	Chemical structure
PVDF (e.g., Solef [®] , Kynar [®]) poly(vinylidene fluoride)	$\left[\text{CH}_2 - \text{CF}_2 \right]_n$
ECTFE (e.g., Halar [®]) poly(ethylene chlorotrifluoroethylene)	$\left[\text{CH}_2 - \text{CH}_2 - \underset{\text{Cl}}{\overset{\text{F}}{\text{C}}} - \text{CF}_2 \right]_n$
PTFE (e.g., Teflon [®]) poly(tetrafluoroethylene)	$\left[\text{CF}_2 - \text{CF}_2 \right]_n$
PFSA (e.g., Nafion [®]) perfluorosulfonic acid	$\left[\text{CF}_2 - \text{CF}_2 \right]_m \left[\text{CF}_2 - \underset{\text{O}}{\overset{\text{O}}{\text{CF}}} \right]_n$ $\begin{array}{c} \text{O} \\ \\ \text{CF}_2 \\ \\ \text{F}_3\text{C} - \text{CF} \\ \\ \text{O} - \left[\text{CF}_2 \right]_y \text{SO}_3\text{H} \end{array}$

stability of ECTFE membranes allows them to be applied in niche applications as ECTFE membranes can withstand continuous operation at temperatures higher than 150 °C in harsh chemical conditions. Although ECTFE membranes are at the development stage with no commercial product in the market, it has a strong potential in organic solvent nanofiltration (OSN) and pervaporation applications.

PTFE polymer is well known under the trademark Teflon[®] with remarkable chemical, mechanical, and thermal stability. Although PTFE has many ideal characteristics for membrane applications, fabricating reliable PTFE membranes has been rather challenging. As no known solvent can dissolve this unique polymer, PTFE membranes are typically fabricated using melt-processing techniques, but its high-melt viscosity has been made a key hurdle to overcome. Nevertheless, commercial MF PTFE membranes are widely used in various industries exploiting their chemical and thermal stability.

PFSA polymers contain sulfonyl branches on PTFE backbone, exhibiting proton conductivity

without losing the high mechanical and thermal stability of PTFE. Naturally, PFSA polymers found large markets in fuel cell industries as proton exchange membranes (PEMs). One of the well-known PFSA polymers carries a trademark Nafion[®]. Although many competitors came into the market after the discovery of Nafion[®] in the late 1960s, it still remains to be the best option in the fuel cell technology.

Gas permeability

Small molecule transport through a dense or nonporous polymeric film is often described by the solution-diffusion model, which has been applied to various membrane separation processes such as reverse osmosis, pervaporation, and gas separation (Graham 1866; Wijmans and Baker 1995; Paul 2004; Baker 2012). Before the solution-diffusion model became well accepted in the 1970s, the pore flow model was also used. The pore flow model is based on a very direct physics interpretation and now is only used by very few people to interpret the reverse osmosis process (Baker 2012).

Based on the solution-diffusion model, the transport of small molecule in the polymer follows three steps, which is illustrated in Fig. 1 for gas separation (Graham 1866; Wijmans and Baker 1995; Lin and Freeman 2006):

1. Feed gas at a high (i.e., upstream) pressure, p_2 , dissolves into the feed side surface of the film.
2. The dissolved gas molecule diffuses through the film due to a concentration gradient.
3. Finally, the gas molecule desorbs from the permeate side surface at the downstream (i.e., low pressure) face of the film.

In the absence of chemical reaction between the gas and polymer, the diffusion of dissolved penetrant is the rate-limiting step in this process, which can be described using Fick's law (Wijmans and Baker 1995; Baker 2012).

The steady-state permeability of small molecule A, P_A , through a film of thickness l is defined as (Wijmans and Baker 1995):

Permeability, Fig. 1 Transport of gases A and B across a polymeric film (Lin and Freeman 2006), which can be described using the solution-diffusion model

$$P_A \equiv \frac{N_A \cdot l}{A_m \cdot (p_2 - p_1)} \quad (1)$$

where N_A is the steady-state flux of component A through the polymer and A_m is the active area for permeation. Permeability can be calculated by directly measuring the parameters shown in Eq. 1. Permeability coefficients of gas and vapor are commonly expressed in Barrers, where 1 Barrer = 1×10^{-10} cm³(STP) cm/(cm² s cmHg) (Stern 1968).

When the permeate pressure is much less than the feed pressure, gas permeability can be written as: (Wijmans and Baker 1995)

$$P_A = D_A \times S_A \quad (2)$$

where S_A is the apparent sorption coefficient or solubility of penetrant A in the polymer. The gas and vapor permeability can be directly measured using the constant pressure-variable volume or constant volume-variable pressure method (Felder and Huvard 1980; Lin and Freeman 2006).

The permeation of the gas through polymer films can also be modeled using molecular

Permeability,

Fig. 2 Schematic of the CO₂ molecule movement from one confined void to another void in a polyimide via random motion (Smit et al. 1992)

dynamic simulation (Smit et al. 1992; Wang et al. 2006). For example, Fig. 2 shows the schematic of CO₂ diffusion in a polyimide matrix. Polymer chains follow random work, which creates temporary voids and channels. The CO₂ molecules can jump from one void to another void via the random motion.

Permeability Coefficient

Haiqing Lin

Department of Chemical and Biological Engineering, University at Buffalo, The State University of New York, Buffalo, NY, USA

The transport property of a penetrant through a film is often characterized by the permeability coefficient. The steady-state permeability coefficient of gas A, P_A , through a film of thickness l is defined as: (Wijmans and Baker 1995)

$$P_A \equiv \frac{N_A \cdot l}{p_2 - p_1} \quad (1)$$

where p_2 and p_1 are upstream (i.e., high) and downstream (i.e., low) pressures, respectively. Permeability coefficients are commonly expressed in Barrers, where 1 Barrer = $1 \times 10^{-10} \text{ cm}^3(\text{STP}) \text{ cm}/(\text{cm}^2 \text{ s cmHg})$ (Stern 1968).

The one-dimensional flux of gas A through the film in the x direction (i.e., N_A) can be described by the solution-diffusion model and Fick's Law (Bird et al. 2002; Ghosal and Freeman 1994):

$$N_A = -D \frac{dC_A}{dx} + w_A(N_A + N_P) \quad (2)$$

where D is the gas diffusion coefficient in the film, C_A is the local concentration of dissolved gas, and w_A is the weight fraction of gas A in the film. N_P is the flux of the membrane, which is typically taken

to be zero. Consequently, Eq. 2 reduces to (Ghosal and Freeman 1994; Koros et al. 1988):

$$N_A = -\frac{D}{1-w_A} \frac{dC_A}{dx} \quad (3)$$

Combining Eqs. 1 and 3 and integrating from $x = 0$ ($C = C_2$) to $x = l$ ($C = C_1$), one obtains:

$$P_A = D_A \frac{C_2 - C_1}{p_2 - p_1} \quad (4)$$

where D_A is the concentration-averaged effective diffusion coefficient in the range for C_1 to C_2 :

$$\begin{aligned} D_A &= \frac{1}{C_2 - C_1} \int_{C_1}^{C_2} \frac{D}{1-w_A} dC \\ &= \frac{1}{C_2 - C_1} \int_{C_1}^{C_2} D_{eff} dC \end{aligned} \quad (5)$$

where D_{eff} is the local effective diffusion coefficient.

In general, it is challenging to directly measure gas average diffusivity. Instead, gas permeability and gas solubility are often measured independently, and gas diffusivity is inferred from these measurements as described below (Lin and Freeman 2006). For simplicity, experiments are often designed so that $p_1 \ll p_2$ and, consequently, $C_1 \ll C_2$. In this limit, Eq. 4 reduces to (Freeman (1999), Wijmans and Baker (1995)):

$$P_A = D_A \times S_A \quad (6)$$

where $S_A = C_2/p_2$ is the apparent sorption coefficient or solubility of penetrant A in the polymer. Therefore, by measuring gas permeability at an upstream pressure of p_2 and solubility at a pressure of p_2 , one can calculate average gas diffusivity, D_A . Gas selectivity, a measure of the ability of polymers to separate two gases A and B, is expressed (Wijmans and Baker 1995):

$$\alpha_{A/B} = \frac{P_A}{P_B} = \frac{D_A}{D_B} \frac{S_A}{S_B} \quad (7)$$

As indicated in Eq. 5, the diffusion coefficient is an average over the concentration range from 0 to C_2 . The local effective diffusion coefficient, D_{eff} , characterizing penetrant diffusivity in the polymer at a penetrant concentration of C_2 , can be evaluated using an equation obtained by taking the derivative of both sides of Eq. 4 with respect to C (Koros and Fleming 1993; Merkel et al. 2000):

$$D_{eff}(C_2) = \left[P_A + p \frac{dP_A}{dp} \right]_{p_2} \left(\frac{dp}{dC_2} \right)_{p_2} \quad (8)$$

which requires the pressure dependence of permeability and solubility to calculate D_{eff} .

Methods to measure pressure dependence of permeability and solubility have been described (Felder and Huvard 1980; Lin and Freeman 2006). Table 1 shows gas permeability coefficients and selectivity of a few commercial gas separation membrane materials, which are arranged in nitrogen permeability coefficients

Permeability Coefficient, Table 1 Gas permeability coefficients and selectivity of several commercial membrane materials at 35 °C, including cellulose triacetate (Puleo et al. 1989), polysulfone (Aitken et al. 1992), polycarbonate (Stern 1994), polyphenylene oxide (Koros et al. 1988), polydimethylsiloxane (Merkel et al. 2000), and Teflon AF2400 (Arcella et al. 2003; Merkel et al. 2006)

Polymer	Permeability (Barrer)				Selectivity	
	N ₂	O ₂	CH ₄	CO ₂	O ₂ /N ₂	CO ₂ /CH ₄
Cellulose triacetate	0.23	1.46	0.20	6.56	6.3	32.8
Polysulfone	0.25	1.4	0.25	5.6	5.6	22
Matrimid	0.32	2.12	0.28	10.0	6.6	35.3
Polycarbonate	0.33	1.6	0.36	6.8	4.8	19
Polyphenylene oxide	3.81	16.8	4.3	61	4.41	14.2
Polydimethylsiloxane	400	800	1,200	3,800	2.0	3.2
Teflon AF2400	490	990	340	2,800	2.0	8.2

from low to high (Koros et al. 1988; Park and Paul 1997; Pauly 1999; Robeson 1991; Stern 1994). The permeability coefficients can vary dramatically depending on the penetrant physical property and the polymer structure.

Permeance

Giuseppe Barbieri

Institute on Membrane Technology, National Research Council of Italy, ITM–CNR, Rende, Italy

Synonyms

Gas permeance

The permeance is a characteristic of a membrane expressing the ability of a species to penetrate and permeate a membrane of a specific thickness. It is an overall coefficient to be used in the evaluation of the flux of any species permeating the membrane as well membrane selectivity.

The driving force at the basis of mass transport through the membrane, in most of the membrane operations such as reverse osmosis, nanofiltration, ultrafiltration, microfiltration, gas separation, membrane distillation, membrane contactors, etc., is a difference of feed and permeate pressures or species partial pressures. This is valid for both dense membranes used in reverse osmosis and gas separation and porous ones utilized in the other operations. In addition, the permeance most often does not depend on the permeation driving force; thus, the following equation defines the flux of each permeating species (*i*th) as the product of permeance and driving force:

$$\text{Flux}_i = \text{Permeance}_i * \text{driving force}_i$$

The reverse of this equation allows the permeance to be calculated; thus, the membrane permeance is evaluated for each species as the ratio between the own flux and the related driving force.

The driving force is calculated as function of the pressure values in the bulks of the feed and permeate streams or volumes for continuous or batch systems, respectively. This means, the permeance has to take into account all the mass transfer resistance encountered by the molecules along the path followed for their permeation from the bulk of the feed side to the bulk of the permeation side. These resistances are those in the film on the feed side, in the separating membrane layer, in the supporting membrane layer, in the support eventually present, in the film on permeation side, and in the fouling as well.

The units of the permeance depend on the permeation mechanism at the basis of mass transport through the membrane. In most of the membrane operations as those before reported for which the driving force is a difference of feed and permeate pressures, the permeance units are:

$$\begin{aligned} & \text{mol m}^{-2}\text{s}^{-1}\text{Pa}^{-1} \\ & (\text{or m}^3\text{m}^{-2}\text{s}^{-1}\text{Pa}^{-1}, \text{ or m}^3\text{m}^{-2}\text{h}^{-1}\text{bar}^{-1}, \\ & \text{ or L m}^{-2}\text{s}^{-1}\text{Pa}^{-1}, \text{ or etc.}) \end{aligned}$$

However, the driving force of the permeation in inorganic membranes, such as the Pd-based and perovskite ones, is the difference of the square root of the pressures on both membrane sides since the hydrogen (see Sieverts' law) or oxygen molecules permeating these membranes are dissociated in atoms before their permeation in the selective membrane layer. Consequently, the permeance units are:

$$\begin{aligned} & \text{mol m}^{-2}\text{s}^{-1}\text{Pa}^{-0.5} \\ & (\text{or m}^3\text{m}^{-2}\text{s}^{-1}\text{Pa}^{-0.5}, \text{ or m}^3\text{m}^{-2}\text{h}^{-1}\text{bar}^{-0.5}, \\ & \text{ or L m}^{-2}\text{s}^{-1}\text{Pa}^{-0.5}, \text{ or etc.}) \end{aligned}$$

Power different from 0.5 is also utilized for the feed-permeate pressure difference when the diffusion in the separating layer is not the only rate-determining step but surface phenomena are significant.

Examples

The permeance of a reverse osmosis membrane, operating under a feed-permeate pressure difference of 50 bar with a water flux of $60 \text{ m}^3 \text{ m}^{-2} \text{ h}^{-1}$, is $60/50 = 1.2 \text{ m}^3 \text{ m}^{-2} \text{ h}^{-1} \text{ bar}^{-1}$.

The permeance of a gas separation membrane having a CO_2 flux of $5 \text{ m}^3 \text{ m}^{-2} \text{ h}^{-1}$ and operating under a feed-permeate partial pressure difference of 10 bar is $500 \text{ dm}^3(\text{STP}) \text{ m}^{-2} \text{ h}^{-1} \text{ bar}^{-1}$ (ca. $62 \text{ nmol m}^{-2} \text{ s}^{-1} \text{ Pa}^{-1}$).

A Pd-based membrane operating at 5 and 1 bar as feed and permeate hydrogen pressures, respectively, shows a hydrogen flux of $300 \text{ nmol m}^{-2} \text{ s}^{-1}$. Thus, hydrogen permeance is ca. $243 \text{ nmol m}^{-2} \text{ s}^{-1} \text{ Pa}^{-0.5}$.

Permeate

Giuseppe Barbieri

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The permeate is the whole mass permeated of the membrane containing the different species which permeated the membrane itself. On the other membrane side with respect to the feed, it is collected in a volume or as a stream, leaving the membrane module in a batch or continuous operations, respectively.

Together with the retentate, the permeate is one of the two outlets of a membrane unit. The other two streams are the feed and, optionally, the sweep.

Permeate Gap Membrane Distillation (PGMD)

Daniel Winter

Fraunhofer Institute for Solar Energy Systems (ISE), Freiburg, Germany

Permeate gap membrane distillation (PGMD) represents a specific configuration of the membrane distillation (MD) process.

In a MD process, a hydrophobic highly porous membrane separates an aqueous feed solution from the distillate. The hydrophobic membrane property prevents the liquid phase from entering the membrane structure; thus, liquid-vapor interfaces are established on both sides of the membrane. By applying a temperature difference, evaporation takes place on the feed (or evaporator) side; the vapor penetrates the membrane pores and condenses on the permeate (or condenser) side. The separation is based on the phase change; thus, the product quality is usually very high and does not depend on feed concentration or the membrane structural properties. The coupled heat and mass transfer through the membrane includes vapor flux, latent heat of evaporation, and conductive heat transfer.

In conventional direct contact membrane distillation (DCMD) process, the heat of evaporation is supplied by the hot feed stream, and the cooling is maintained by the cold stream, respectively.

In permeate gap membrane distillation (PGMD) process, a third channel is introduced by an additional non-permeable foil, similar to air gap membrane distillation (AGMD). The basic PGMD channel arrangement is given in Fig. 1.

In PGMD, usually this channel is filled with permeate during operation. One significant advantage of this arrangement is the separation of permeate from the cooling fluid. Therefore, the coolant can be any other liquid, such as cold feed.

The presence of the permeate gap and the non-permeable foil introduce additional heat transfer resistances, which lead to a reduction of the effective temperature difference across the membrane. This heat transfer resistance is to be minimized, by designing a very thin permeate gap and using thin foils.

For special applications this concept can even be further developed, e.g., by introducing a second foil at the feed side. Here, the heating function can be decoupled from the feed solution as well (Hausmann et al. 2011).

In module design, the PGMD concept provides the opportunity for internal heat recovery. Modules are usually designed based on plate and frame or spiral wound concepts.

Figure 2 shows the channel arrangement for a PGMD module with integrated heat recovery. The PGMD channel arrangement is transferred into a compact spiral package. Full-scale modules of this type were developed and fabricated at Fraunhofer ISE (Winter et al. 2011). The total

Permeate Gap Membrane Distillation (PGMD), Fig. 1 Basic channel arrangement and temperature profile for PGMD (Winter et al. 2011)

Permeate Gap Membrane Distillation (PGMD), Fig. 2 Principle channel arrangement of a spiral wound PGMD module (Winter et al. 2011)

membrane area is 5–15 m². The module concept goes back to a patent of W. L. Gore from 1985 (Gore et al. 1985).

This type of module is quite suitable to follow the transient behavior of thermal energy input from renewable sources. Thus, an integration to solar thermal collectors or waste heat is easily applicable. Various demonstration plants for desalination using PGMD spiral wound modules have already been tested in the field (Raluy et al. 2012).

Permeating Flux

Giuseppe Barbieri

Institute on Membrane Technology, National Research Council of Italy, ITM–CNR, Rende, Italy

All the species permeating a membrane generate a stream passing through the membrane, a stream characterized by a flow rate according to the actual operating conditions. A permeating flux is defined for this stream as the ratio of the permeating flow rate and the membrane area.

$$\text{Permeating Flux} = \frac{\text{Permeating Flow Rate}}{\text{Membrane Area}}$$

The permeating flux can be defined as well for *i*th species as the ratio of the flow rate of the referred species and the membrane area.

$$\text{Permeating Flux}_i = \frac{\text{Permeating Flow Rate}_i}{\text{Membrane Area}}$$

It is a fraction of the total permeating flux and can be expressed as product of the molar fraction of the *i*th species and the permeating flux of all the species.

$$\text{Permeating Flux}_i = \text{Molar Fraction}_i \cdot \text{Permeating Flux}$$

The permeating flux can be defined for each elementary membrane area element or for the whole membrane area. In the first case, it is a function of the spatial coordinates such as, for instance, the

membrane length. In the latter case, the permeating flux corresponds to the integration of the permeating flow rate on the whole membrane area of the elementary one divided for the whole membrane area.

Permeation Number

Giuseppe Barbieri

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The permeation number expresses (Brunetti et al. 2010), for each species, a comparison (ratio) between two main transport mechanisms involved in a membrane separation unit:

1. The mass transport through the membrane
2. The convective mass transport for feeding the membrane unit

For the i th species, it is given by the equation

$$\text{Permeation Number}_i = \frac{\text{Permeance}_i \text{ Membrane Area} \text{ Feed Pressure}}{\text{Feed Molar Fraction}_i \text{ Feed Flow Rate} \text{ Pressure Ratio}}$$

It is a dimensionless number to be used in sizing the permeation unit. A low value means a low fraction of the referred i th species can pass through the membrane; vice versa, a high value means a large fraction of i will be in the permeate stream.

A value of zero means no membrane separation, that is, permeance equals to zero or equivalently no membrane area available for permeation.

The pressure ratio is the ratio of the feed to the permeate pressures.

Permeation Reduction Maps

Alessio Caravella

National Institute of Advanced Industrial Science and Technology – Research Institute for Innovation in Sustainable Chemistry, ISC-AIST, Tsukuba, Ibaraki, Japan

With reference to the definition of the overall permeation reduction coefficient (PRC) – whose definition is briefly recalled in Eq. 1 – the so-called permeation reduction maps refer to diagrams where PRC is plotted as a function of several operating conditions, like hydrogen partial pressure, temperature, total pressure, and membrane geometrical parameters.

$$[\text{Flux}]_i^{\text{Actual}} = (1 - PRC_i) \times [\text{Flux}]_i^{\text{Max}} \quad (1)$$

The usefulness of the permeation reduction maps consists in reading a value of PRC based on the operating conditions of interest and using it directly in Eq. 1 to evaluate the actual flux, i.e., the flux reduced from the maximum one by the effect of the unwanted phenomena, for example, concentration polarization and inhibition.

Permeation reduction maps can be built both by experimental campaigns and by computer simulations of the hydrogen permeation process.

An example of *permeation reduction map* including the effect of concentration polarization and inhibition by CO is shown in Fig. 1 for hydrogen permeation through Pd-based membranes. In this figure, generated by simulation, PRC is depicted as a function of hydrogen molar fraction and CO partial pressure for different values of total upstream (feed) pressure (Caravella et al. 2010).

Permeation Reduction Maps, Fig. 1 Example of permeation reduction map in terms of permeation reduction coefficient as a function of hydrogen molar fraction in the upstream and CO partial pressure for different values of upstream pressure evaluated by computer simulation in the conditions reported in the legend (Adapted from Caravella et al. (2010))

Membrane permselectivity; Rejection

Permselectivity in Dense Membranes

Permselectivity is the most important membrane property to evaluate the quality of membrane separation. The capability of a membrane to separate different components from each other can be expressed by selectivity. Considering a two-component mixture *A* and *B*, the selectivity is given by the ratio of their permeability coefficients as follows (Strathmann et al. 2006):

$$S_{A,B}^p = \frac{P_A}{P_B}$$

Here $S_{A,B}^p$ is the permselectivity of a membrane toward components *A* and *B*, and P_A and P_B are their permeability coefficients. Materials with high permeability and selectivity are desirable. Higher permeability decreases the amount of membrane area required to treat a given compound, thereby selectivity results in higher purity product.

For dense membranes, the permeability coefficient (P) can be expressed by the following equation:

$$P = D \times S$$

where D and S are the diffusivity and the solubility coefficients of the gas species, respectively.

Permselectivity in Porous Membranes

For porous membranes, the hydraulic permeability (L_p) is defined as a volume of permeate passing for the unit time through a unit of membrane surface area under a certain hydrostatic pressure:

$$L_p = \frac{V}{At\Delta P}$$

where V is the permeate volume (L), t is the time (h), and ΔP is the transmembrane pressure (bar). For the processes based on porous membranes, the quality of separation that the membrane provides can be expressed in terms of rejection, which is given by:

$$R_A = 1 - \frac{C_A^{\text{permeate}}}{C_A^{\text{feed}}}$$

Here R_A is the rejection of component A by the membrane and C_A^{permeate} and C_A^{feed} are the concentrations of the component A in the two phases. The value of rejection varies between 0 (no selectivity) and 1 (complete retention of the solute).

Permselectivity in Ion-exchange Membranes

In ion-exchange membranes, the permselectivity describes the degree to which an ion of one charge passes through the membrane, while an ion of the opposite charge is retained. This parameter can be calculated from the transport number (T) of the counter- and co-ions in the membrane and the outside solutions. The permselectivity of ion-exchange membrane (Ψ) is given as follows:

$$\Psi^m = \frac{T_{\text{cou}}^m - T_{\text{co}}}{T_{\text{co}}}$$

The transport numbers (T) are defined by:

$$T_i = \frac{z_i J_i}{\sum_i z_i J_i}$$

Here z is the valence, J is the flux, the subscript i refers to cation or anion, the subscripts cou and co refer to counter- and co-ions, and the subscript m refers to ion-exchange membrane. The permselectivity of the membrane approaches zero when the transport numbers of the ions within the membrane are identical to those in the electrolytic solution.

The permselectivity of a membrane is determined by the ratio of the flux of specific components to the total mass flux through the membrane under a given driving force. In ion-exchange membranes, the permselectivity is related to the transport of electric charges by the counterions (Strathmann et al. 2006; Tonaka 2015). The permselectivity of an ion-exchange membrane, i.e., its charge selectivity, is determined by the concentrations of counter- and coions in the membrane, which again depends mainly on the ion-exchange capacity of the membrane and the ion concentration in the outside solutions because of the Donnan exclusion as discussed earlier. The permselectivity can be calculated from the transport number of the counter- and coions in the membrane and the outside solutions.

The permselectivity of a membrane is given by:

$$\Psi^m = \frac{T_{\text{cou}}^m - T_{\text{co}}}{T_{\text{co}}} \quad (1)$$

The transport numbers are defined by:

$$T_i = \frac{Z_i J_i}{\sum_i z_i J_i} \quad (2)$$

Here Ψ is the permselectivity, T is the transport number, z is the valence, and J is the flux; the subscript i refers to cation or anion, the subscripts cou and co refer to counter- and coions, and the superscript m refers to the ion-exchange membrane.

In a cation-exchange membrane, the cation is the counterion and the anion the coion, while in an anion-exchange membrane, the anion is the counterion and the cation the coion.

An ideal permselective cation-exchange membrane, for instance, would be permeable for positively charged cations (counterions) only. The permselectivity of a membrane approaches zero when the transport numbers of the ions within the membrane are identical to those in the electrolytic solution.

To determine the membrane permselectivity, respectively, two methods can be applied. The first method is based on a measurement of the increase in concentration of certain ions in the concentrate and the decrease in the dilute solution during electrodialysis of a test solution and by measuring the amount of current passing through the unit. From the current utilization, the permselectivity of the membrane can be calculated. With this “dynamic” measurement, water transport due to electroosmosis and osmosis is taken into account, and the “true” membrane permselectivity is obtained. The dynamic method, however, is rather time-consuming and affected by concentration polarization at the membrane surfaces.

A faster “static” method for the determination of membrane permselectivities, which is not affected by boundary layer transport phenomena, is based on the measurement of the potential gradient across a membrane which separates two electrolyte solutions of different concentrations. The static method, however, does not take the water transport through the membrane into account and is referred to as “apparent” permselectivity.

The potential between two electrolyte solutions of different concentrations, i.e., the membrane potential, consists of the two Donnan potentials between the membrane and the adjacent solutions and the diffusion potential across the membrane.

$$\varphi_m = \varphi_{\text{dif}} + \varphi_{\text{Don}}^1 - \varphi_{\text{Don}}^2 \quad (3)$$

Here φ is the potential; the subscripts m , dif, and Don refer to membrane, diffusion, and Donnan potential; and the superscripts 1 and 2 refer to the different solutions.

For a completely permselective membrane, the diffusion potential is zero. The membrane potential is then given by the difference in the two Donnan potentials. For a not strictly permselective membrane, the diffusion potential must be added to the Donnan potential difference to determine the membrane potential. For a single, monovalent salt such as KCl as an electrolyte, the membrane potential between two solutions of the same electrolyte but different concentration can be derived from the general flux equation with the boundary conditions of $\Delta P = 0$ and $I = 0$. By introducing several approximations, such as negligible osmotic flow between the two solutions, constant ion mobility, small concentration gradients across the membrane phase, etc., the potential difference between solutions can be expressed by:

$$\begin{aligned} \varphi_m &= (T_{\text{cou}}^m - T_{\text{co}}^m) \frac{RT}{F} \ln \frac{a_s^1}{a_s^2} \\ &= (2T_{\text{cou}}^m - 1) \frac{RT}{F} \ln \frac{a_s^1}{a_s^2} \end{aligned} \quad (4)$$

For a strictly permselective membrane, the transport number of the counterion is 1, i.e., there is no salt diffusion through the membrane, and the membrane potential is given by:

$$\varphi_{m,\text{sp}} = \frac{RT}{F} \ln \frac{a_s^1}{a_s^2} \quad (5)$$

Here φ_m and $\varphi_{m,\text{sp}}$ are the membrane potentials of a real and a strictly permselective ion-exchange membrane, T_{cou}^m and T_{co}^m are the transport numbers of the counter- and coions in the membrane, a_s is the activity of the salt solution, R is the gas constant, T is the temperature, F is the Faraday constant, and the superscripts 1 and 2 refer to the two solutions separated by the membrane.

The counterion transport number in a not strictly permselective membrane is obtained as follows:

$$\frac{\varphi_m}{\varphi_{m,sp}} = 2T_{\text{cou}}^m - 1 \quad (6)$$

and

$$T_{\text{cou}}^m = \frac{\frac{\varphi_m}{\varphi_{m,sp}} + 1}{2} \quad (7)$$

Introducing Eq. 7 into Eq. 1 and rearranging give the permselectivity of a cation-exchange membrane as a function of the membrane potential:

$$\Psi^m = \frac{\frac{\varphi_m}{\varphi_{m,sp}} + 1 - 2T_{\text{cou}}}{2T_{\text{co}}} \quad (8)$$

Here Ψ^m is the apparent permselectivity of an ion-exchange membrane.

For a salt such as KCl, the transport numbers of cation and anion in the solution are nearly identical, i.e., $T_{\text{cou}} \cong T_{\text{co}} \cong 0.5$, and the permselectivity can be expressed to a first approximation by:

$$\Psi^{\text{cm}} \cong \frac{\varphi_{m,\text{real}}}{\varphi_{m,sp}} \quad (9)$$

Permselectivity of Ion-Exchange Membranes,

Fig. 1 Schematic drawing illustrating the test cell for determining the membrane potential

The membrane potential is measured with reference electrodes in a test cell consisting of two chambers separated by a membrane as illustrated in Fig. 1.

Both chambers are filled with the same electrolyte solution, e.g., KCl, but with different concentrations, i.e., 0.5 and 1 mol L⁻¹. To avoid a concentration change due to diffusion, the two solutions are well mixed. Then the membrane potential is measured and divided by the potential of a strictly permselective membrane.

Membrane Permeation Selectivity for Different Counterions

The permeation of counter- and coions in ion-exchange membranes is generally quite different, and the counterion permselectivity is close to 1. It is determined mainly by the Donnan exclusion of the coions. However, certain ion-exchange membranes also show permeation selectivity for different counterions. This selectivity is determined mainly by the mobility of the different ions in the membrane, i.e., by the ion size and the structure of the membrane.

The permeation selectivity of different counterions is determined by measuring the fluxes of counterions in a mixture of electrolytes having different counterions but identical coions with reversible electrodes or in a conventional electro-dialysis test. The permeation selectivity of a membrane for different counterions is given by the ratio of their fluxes through the membrane which is identical to the ratio of their transport numbers in the membrane.

Perovskite Membranes

Lidietta Giorno¹ and Heiner Strathmann²

¹Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

²Universität Stuttgart, Institute of Chemical Process Engineering Stuttgart, Baden-Württemberg, Germany

Perovskite-type membranes have good electron conductivity and oxygen permeability. They have potential applications for oxygen separation from air or oxygen-containing gas mixtures as well as membrane reactors for partial oxidative reactions. Due to mixed-oxygen ion-electron conducting properties, ceramic membranes made of such materials are permeable to oxygen at

Perovskite Membranes, Fig. 1 Membrane perovskite preparation methods: (a) Citrate method; (b) Solid-state method; (c) Coprecipitation method

Perovskite Membranes, Fig. 2 Preparation of $\text{Ba}_{0.5}\text{Sr}_{0.5}\text{Co}_{0.8}\text{Fe}_{0.2}\text{O}_{3-\delta}$ (BSCFO) membrane

elevated temperature without the need for outside electrical circuitry for electron transportation, which is necessary in traditional oxygen pumps.

The traditional methods to synthesize perovskite powder are citrate, solid-state, and coprecipitation method (Qi et al. 2000). They are illustrated in Fig. 1a–c.

A recent method to prepare perovskite $\text{Ba}_{0.5}\text{Sr}_{0.5}\text{Co}_{0.8}\text{Fe}_{0.2}\text{O}_{3-\delta}$ (BSCFO) powders has

been developed by Shao et al. (2000a, b) as illustrated in Fig. 2. The prepared powder is then pressed into disks in stainless steel molds under hydraulic pressure. The disks are then sintered in a SiC muffle oven at a temperature between 1040 °C and 1500 °C for 2–5 h with a heating and cooling rate of 1 °C min⁻¹ and 2 °C min⁻¹, respectively. Wang et al. (2002) reported about the possibility to obtain also tubular membranes by

extrusion method. The ceramic powder is first mixed with additives (solvents, dispersant, plasticizer, etc.) to improve fluidity of the slip mixture. Then, the slip is extruded through a die at a high pressure to produce the tube-shape membrane. Finally, to remove the organic additives, the membrane is heated at 5 °C/h in the temperature range of 100–450 °C.

Perovskite Powder Preparation Methods

Guttorm Syvertsen-Wiig
Ceramic Powder Technology AS, Tiller, Norway

Synonyms

Conventional ball milling and calcination; Hydrothermal synthesis; Pertraction coprecipitation and calcination; Spray-pyrolysis

Powders used to manufacture thin films by mainstream methods (e.g., spray coating or screen printing) require properties such as high purity, small particle size, and good sinterability. Therefore, liquid-based methods including spray pyrolysis, hydrothermal synthesis, and coprecipitation

are preferred over low-cost methods (i.e., solid-state synthesis).

Spray pyrolysis is a solution-based method in which elements are dissolved and stabilized in stoichiometric ratios. The solution is fed through a nozzle into a furnace, typically operated at 600–1,000 °C. The liquid evaporates, leaving hollow spheres of metal oxides and organic residues which are collected in a cyclone. Parameters like temperature, concentration, amount of stabilizing agents, and time of flight of the particles influence particle size and the degree of phase purity of the resulting powders. The particles of the resulting powders are agglomerates, usually 1–100 µm in diameter, consisting of small crystallites in the range of 10–100 nm. In most cases, further heat treatments are needed to obtain the desired phase and milling to break up the agglomerates.

Coprecipitation is another solution-based powder synthesis route. Precipitation in its simplest form involves a precursor (e.g., metal salt or alkoxide) containing the desired element which is dissolved in a liquid and brought over the saturation threshold, leading to a supersaturated solution where the solute start to precipitate (hydrolysis). Usually, initial nucleation is induced by either evaporation indirectly increasing the concentration or adding a chemical reagent. Concentration, pH, chemical composition, additives, and temperature are factors which control both nucleation and particle growth. When a sufficient number of nuclei have been formed, the concentration decreases to below the saturation threshold, and the particles start to grow. To produce uniform particles, one desire to have rapid nucleation and slow particle growth. When several elements are precipitated simultaneously, it is often referred to as coprecipitation. In this case, the elements start to precipitate under different conditions, and it is often challenging to find optimal conditions to avoid a mixture of different phases, although further heat treatments are necessary in most cases.

Hydrothermal synthesis is similar to coprecipitation, where nucleation and grain growth are reached through elevated temperature and pressure. The solution is placed inside an

autoclave lined with a plastic coating to avoid corrosion and reactions with the side walls and heated to 100–375 °C which typically leads to pressures up to 20 MPa. The particles are very small, typically 10–20 nm, narrow size distribution and high phase purity, and a range of crystal shapes can be grown. However, drying of the powders after synthesis can lead to hard agglomerates which deteriorate the sintering properties. Upscaling of hydrothermal synthesis to industrial production is a challenge when large amounts are sought.

Calcination is often required after synthesis since most as-prepared powders are multiphase materials consisting of oxides, nitrates, carbonates, and/or other organic species; thus, the powders are heat treated to form a single-phase perovskite. During the calcination step, nitrates and carbonates decompose into oxides, and the cations diffuse within the material forming homogeneous oxide particles. Depending on the material system, controlled atmospheres (i.e., pO_2 , pH_2O) are sometimes necessary to obtain the desired phase by manipulating the oxidation state of the elements and the water (or proton) uptake in the structure. In most cases, the temperature during calcination aims to be as low as possible to prevent particle coarsening which again hinders sintering in later steps of membrane processing.

By milling, agglomerates formed during synthesis can be disintegrated into smaller particles. The most commonly used method today is wet ball milling, in which powders are mixed with a liquid and grinding media in a rotating container. The liquid is often water, ethanol, isopropanol, or acetone, depending on the elements of the perovskite to prevent dissolving the material. The grinding media consist of balls or cylinders made of hard ceramic materials such as yttrium-doped zirconia, alumina, or silicon nitride. After milling, the slurry is dried and powder sieved to the desired particle size distribution. Subsequently, a short thermal treatment is often necessary to burn off organic residuals added during milling, and one should be aware that the powder may be subject to some contaminants from the grinding media. Other methods to break up agglomerates include jet, attrition, and vibrator milling.

Persistent Organic Pollutant

Geoffroy Lesage

Institut Européen des membranes, IEM,
UMR-5635, Université de Montpellier, ENSCM,
CNRS, Montpellier, France

Persistent organic pollutants (POPs) are organic compounds that are resistant to environmental degradation through chemical, biological, and photolytic processes (Ritter et al. 2007). Because of this, they have been observed to persist in the environment, to be capable of long-range transport, to bioaccumulate in human and animal tissue, to bioaccumulate throughout food chains, and to produce potential human health risks and ecological disturbances.

Many pollutants have been classified as POPs; most of them are halogenated organics and aromatic and aliphatic hydrocarbons. In the field of water treatment, main POPs found in aquatic environments are pesticides, toxins, plastifiers, or pharmaceuticals and personal care products (PPCPs).

Various impacts from different POPs have been identified, the most eye catching being the endocrine-disrupting compounds (EDCs) which can apparently cause fish to change gender. Other POP health impacts have been identified to the reproductive system, the central nervous system, or the immune system (Damstra 2002).

Current studies aimed at controlling and decreasing POP release into the environment (El-Shahawi et al. 2010). However, proper removal techniques of POPs from the environment are still unclear, and different mechanisms could explain the release of POPs into the nature: biosorption on sludge and persistence in the dissolved phase or volatilization. Indeed, for certain volatile POPs like BTEX (benzene, toluene, ethylbenzene, and xylene) or low molecular mass PAH (polyaromatic hydrocarbon), bioavailability could be reduced by volatilization during aerated period in an activated sludge bioreactor (Mozo et al. 2012). Moreover chlorination of remaining compounds in final effluent can form chlorinated

derivatives that are suspected of being carcinogenic to humans (chlorinated hydrocarbons). The acute and long-term toxicity effects of chlorinated compounds on aquatic life have been well documented and have been identified as a major environmental and health issue.

While incurring an impact even at exceedingly low concentrations (tens of nanograms per liter), POPs appear to be well removed by advanced wastewater treatment processes such as activated carbon adsorption, membrane bioreactors (MBRs), nanofiltration and reverse osmosis, and advanced oxidation process (AOP) (Joss et al. 2005).

Because of the increased solid retention time and concentration, MBRs provide more intensive bio-treatment than a conventional activated sludge process, leading to better POP removal efficiency (Hai et al. 2014).

AOP process efficiency on POPs has to be well designed due to the fear that more toxic by-products may result from incomplete oxidation techniques (ozonation, Fenton process). Furthermore, total treatment costs for achieving complete removal of POPs and carbon footprint associated with it could limit the development of such advanced treatment process (James et al. 2014).

Current efforts are more focused on banning the use and production of POPs worldwide rather than removal of POPs.

Pervaporation (PV)

Bart Van der Bruggen

Department of Chemical Engineering, Process Engineering for Sustainable Systems (ProcESS), KU Leuven, Leuven, Belgium

Pervaporation is a membrane separation process, in which components from a liquid mixture are selectively transported through a dense or microporous membrane. Pervaporation was mentioned for the first time in 1917 by Kober in a publication reporting on the selective permeation of water from aqueous solutions of albumin and toluene through cellulose nitrate films. "Pervaporation" is a contraction of "permselective evaporation." The permselectivity originates from the membrane itself, which selectively transports components from the feed mixture, due to differences in (mainly) hydrophilicity and molar size.

Pervaporation (PV),
Fig. 1 Pervaporation
 modules in series with
 intermediate heat
 exchangers

Evaporation is obtained by a low partial pressure at the permeate side of the membrane, either by using a vacuum or a sweep gas stream. The heat of vaporization of the permeating components has been supplied to the feed. In an industrial setup, this heat is supplied by intermediate heat exchangers installed between a number of pervaporation modules in series. This is shown in the figure below (Fig. 1).

Permeation through the membrane in pervaporation can be described in two different ways. The first is the use of pore flow model (and derived models), developed by Okada and Matsuura (1991). The basic assumption of such models is that the membrane is considered to be a bundle of straight, cylindrical pores distributed across the surface layer of the membrane. Transport (and thus, separation) is achieved by liquid permeation followed by vapor permeation through nanometer-scale pores, due to a pressure difference over the membrane. Convective transport is assumed within the pores with an intermediate phase change due to the vacuum at the permeate side or the use of a sweep gas (Shieh and Huang 1998a, b; Lipnizki and Trägårdh 2001). The second approach is the solution-diffusion model, developed by Graham and introduced to pervaporation by Binning et al. (1961). In this model, the membrane is considered to be nonporous so that transport occurs only by diffusion and not by convection. Transport of a component from the feed solution through the membrane occurs by (1) sorption onto the

membrane, (2) diffusion through the membrane, and (3) desorption from the membrane. The driving force is a difference in chemical potential (due to a partial pressure or activity difference) between feed and permeate side (Lipnizki and Trägårdh 2001).

Three types of separations should be distinguished for pervaporation. In hydrophilic pervaporation, small fractions of water (typical range 1–10 %) are removed from organic solvents, using hydrophilic polymers (typically polyvinyl alcohol (PVA), but also other polymers can be used) or ceramic membranes. Hydrophobic pervaporation makes use of polymeric membranes (hydrophobic, such as polydimethylsiloxane or PDMS) with preferential transport of nonpolar solvents, which can be used to remove organics from an aqueous matrix. The third type of applications is organic-organic separations, which require special membranes allowing to distinguish between different organic solvents; an example is PTMSP (Claes et al. 2011). The most important industrial application is the dehydration of alcohols, although research efforts also indicate a great potential in the water and wastewater treatment sector, in the food and biotechnology industry, and in the chemical industry.

With regard to large-scale industrial application, the earliest mention of an operating pilot plant dates back to 1982 as a demonstration unit for alcohol dehydration was designed to produce 1,200 l per day of 99.2 wt.% ethanol.

This unit clearly demonstrated the low energy consumption of pervaporation compared with that of conventional dehydration of ternary azeotropic distillation after addition of benzene (Feng and Huang 1997; Kujawski 2000; Jonquière et al. 2002).

A membrane separation process closely related to pervaporation is vapor permeation. The only difference concerns the feed, which is a mixture of vapors or vapors and gases in vapor permeation, in contrast to the liquid feed in pervaporation.

Pervaporation for Chloroform Separation

Tadashi Uragami

Organization for Research and Development of Innovative Science and Technology (ORDIST), Kansai University, Suita, Osaka, Japan

Chloroform/water-selective membranes are effective for the removal of chloroform in water. These membranes can be contributed to the environmental problem.

Removal of chloroform in an aqueous chloroform solution through the poly(methylmethacrylate)-poly(dimethylsiloxane) (PMMA-g-PDMS), poly(ethylmethacrylate)-PDMS (PEMA-g-PDMS), and poly(*n*-butylmethacrylate)-PDMS (PBMA-g-PDMS) graft copolymer membranes was investigated by pervaporation (PV).

Figure 1 shows the results of PV for an aqueous solution of 0.02 wt.% chloroform through the graft copolymer membranes. The chloroform permselectivity of PMMA-g-PDMS and PEMA-g-PDMS membranes increased dramatically at a DMS content of more than about 40 and 70 mol%, respectively. It is noticeable that the benzene and chloroform permselectivity and the normalized permeation rates for the graft copolymer membranes changed remarkably at the same DMS content. These results suggest that the PMMA-g-PDMS and PEMA-g-PDMS membrane structure changed at the corresponding DMS content. On the other hand, the PBMA-g-PDMS membrane showed a gradual increase in chloroform permselectivity and normalized permeation rate with increasing DMS content. From the above results, it was found that the structural change in the PBMA-g-PDMS membrane with variations in DMS content was quite different from that of the PMMA-g-PDMS and PEMA-g-PDMS membranes (Uragami et al. 2001).

The permeation and separation characteristics of chloroform from water by PV through cross-linked PDMS membranes prepared from

Pervaporation for Chloroform Separation, Fig. 1 Effect of the DMS content on the chloroform concentration in the permeate and normalized permeation rate for an aqueous solution of 0.02 wt.% chloroform through the PMMA-g-PDMS (○), PEMA-g-PDMS (●), and PBMA-g-PDMS (□) membranes by pervaporation

PDMSDMMMA and divinyl compounds, such as EGDM, DVB, DVS, and DVF, were studied (Ohshima et al. 2005). Those membranes showed high chloroform selectivity and permeability. Both chloroform/water selectivity and permeability were affected significantly by the divinyl compound. Furthermore cross-linked PDMSDMMMA membranes showed the highest chloroform/water selectivity. The chloroform/water selectivity was mainly governed by the solubility rather than the diffusion selectivity. With increasing downstream pressure, the chloroform/water selectivity of all cross-linked PDMSDMMMA membranes increased, but the permeability decreased. A -PDMSDMMMA-DVF membrane exhibited a normalized permeation rate of $1.9 \times 10^{-5} \text{ kgm (m}^2\text{h)}^{-1}$ and a separation factor for chloroform/water of 4,850, yielding a separation index of 9,110.

PV experiments were carried out using poly(vinylidene fluoride) (PVF₂) flat-sheet membranes with different thickness for chloroform/water mixtures (Khayet and Matsuura 2004). In Table 1 the permeation rates for chloroform and water and the separation factor, $\alpha_{\text{CH}_3\text{Cl}/\text{H}_2\text{O}}$, are listed. With increasing membrane thickness, the separation factor for the chloroform/water increased, and the permeation rates for water and chloroform decreased. In fact, the selectivity of the PVF₂ membranes is associated not only with the surface characteristics but also with the diffusion through the membrane bulk structure.

Pervaporation Hybrid System

Bart Van der Bruggen

Department of Chemical Engineering, Process Engineering for Sustainable Systems (ProcESS), KU Leuven, Leuven, Belgium

Synonyms

Pervaporation-based hybrid system

A hybrid system based on pervaporation refers to an integrated entity comprising a pervaporation unit for separation and a second unit in which either a reaction is carried out or a separation with a different method than pervaporation. The

integration by recycling one stream from the pervaporation unit and another stream from the second unit to the pervaporation unit is an essential aspect of the hybridization (without a recycle stream, the system would rather be a separation-separation or reaction-separation sequence) (Van der Bruggen 2010). A hybrid system should have a performance superior to the performance of the sum of the individual processes, which should not be able to carry out the overall process as a stand-alone system (although this is usually understood in the sense that none of the individual processes is able to carry out the overall process *in an economical way*).

Lipnizki et al. (1999) categorize pervaporation hybrid systems into two types, i.e., separation-type and reaction-type hybrid processes. The latter are denoted as R-type hybrid systems; the pervaporation unit can remove either the desired reaction product from the reactor or from a recycle loop (R1-type hybrid system) or a side product (R2-type hybrid system), which is often water. This is shown in Fig. 1 (Lipnizki et al. 1999). R-type hybrid systems with a pervaporation unit for separation are also referred to as pervaporation membrane reactors. R1-type hybrid systems are typical (but not exclusive) for bioconversions, in which the conversion can be enhanced by removal of the conversion product. For example, in the production of bioethanol, the product ethanol acts as an inhibitor for bacterial activity when the concentration becomes too high. Removal of ethanol allows for continuous biological activity,

Pervaporation Hybrid System, Fig. 1 R-type (reaction) hybrid processes: (a) type R1 (removal of reactor product) and (b) type R2 (removal of by-product) (Lipnizki et al. 1999)

Pervaporation Hybrid System, Fig. 2 Integration of pervaporation and distillation in different hybrid configurations

which enhances the yield of ethanol significantly. R2-type pervaporation hybrid systems are typical for equilibrium reactions, in which the yield is enhanced by the removal of a by-product of the reaction. According to the principle of Le Châtelier-Braun, the reaction equilibrium would then shift toward a higher conversion; the net result is that the yield of the desired product is substantially higher, allowing even for full conversion. The most studied examples are esterification reactions, in which an ester is produced from the reaction of an acid with an alcohol. The side product in these reactions is water, which can be easily removed from the reaction medium by a hydrophilic pervaporation membrane. Esterification reactions are often carried out with acetic acid (Van der Bruggen 2010). Pervaporation-assisted esterification of ethanol and acetic acid is often studied, but many other reactions are similar. The principle was patented in 1995 (Datta and Tsai 1995) for the esterification of lactic acid, propionic acid, butyric acid, acetic acid, and succinic acid (and combinations thereof) with an alcohol, including the reaction of acetic acid and ethanol, aided by the use of a pervaporation membrane.

The separation-type hybrid systems based on pervaporation typically combine pervaporation with distillation. Both processes can in principle be used for the same kind of separations, but the separation mechanisms are totally different (based on a difference in volatility for distillation and on a difference in membrane affinity for pervaporation), so that a combination is logical to overcome difficult points in the individual processes. Different configurations based on

integration of pervaporation with a distillation column are shown in Fig. 2 (Van der Bruggen 2010).

The most common difficulties in separations are azeotropic points in distillation, which require complex and energy-intensive solutions when using distillation alone, but are easy in a hybrid setup in which pervaporation is used to overcome the azeotrope. A typical example is the production of ethanol from ethanol-water mixtures. The azeotrope at a concentration of ethanol of ca. 96 % can be overcome by distilling to, e.g., 90 % and continuing with pervaporation for purification of the distillate (and recycling the water-richer retentate back to the distillation column). Various hybrid pervaporation systems can be developed, with a (smaller) distillation column for the final ethanol purification, or a second, more selective pervaporation membrane separation.

Pervaporation in Natural Aroma Processing

Alberto Figoli

Institute on Membrane Technology, National Research Council of Italy, ITM–CNR, Rende, Italy

Natural aromas are extremely volatile organic compounds. The aromatic fraction reveals information on the quality of the food and it is directly related to its odor, texture, and taste. Aroma compounds are generally present in very low concentrations (1–20 ppm) even if the complex of the single aromatic compounds in a fruit is very high. Studies of different types of fruits, in fact, indicate that more than 6,000 compounds are responsible of their aroma (Aroujalian and Raisi 2007) belonging to different chemical classes such as alcohols, ketones, aldehydes, esters, carboxylic acids, and phenols. Aroma recovery for food and cosmetic industries continues to be a great challenge for economic and quality reasons (Sampranpiboon et al. 2000). In the fruit juice industry, for instance, where a concentration step is needed, a loss and a degradation of aroma compounds, due to the thermal treatment, can occur. For this reason, in order to restore the original flavor quality of the final product, it is necessary to recover and add these aromatic compounds back to the concentrated juice (Pereira et al. 2006). In this context, pervaporation (PV) is a novel method that can be applied for aroma recovery from diluted aqueous solutions. Pervaporation, in fact, is based on the chemical-physical interaction between membrane material and the components present in the feed. Hydrophobic pervaporation, in particular, is applied to aroma recovery by using hydrophobic membrane materials such as polydimethylsiloxane (PDMS) and polyoctylmethyl siloxane (POMS) (Lipnizki et al. 2002). Compared to other traditional techniques, such as distillation, adsorption, air stripping, and solvent extraction, pervaporation offers numerous advantages: high selectivity, low energy requirement, no chemical addition, and

low-operating temperature. Pervaporation performances are evaluated by taking in consideration the permeate flux and selectivity. Up to now most studies focused on the separation of model binary or multicomponent solutions and just a few of them were based on real feed obtained from fresh fruits (Figoli et al. 2010). Aromas have been isolated by pervaporation from several fruits such as pineapples, grapes, kiwis, strawberries, oranges, and pomegranates. During the last few years, most of the research on aroma recovery has been carried out on laboratory scale. Pervaporation scale-up, in fact, is still underdeveloped due to several limitations mainly due to the membranes and modules, which are not sufficient selective and economic.

Pervaporation Membrane

Bart Van der Bruggen

Department of Chemical Engineering, Process Engineering for Sustainable Systems (ProcESS), KU Leuven, Leuven, Belgium

A membrane for pervaporation is a microporous or dense membrane, which selectively transports

components from a liquid mixture due to differences in sorption in the membrane matrix and in diffusion through the membrane to the permeate side. Dense membranes have in principle no pores, whereas microporous membranes have pores in the order of magnitude of 1 nm. The difference, however, is small since the free volume in dense membranes can yield pathways with sizes in the same range as microporous channels.

In general, three types of membranes can be distinguished: (1) hydrophilic membranes, which preferentially transport polar solvents, in particular water, (2) hydrophobic membranes, which preferentially transport nonpolar solvents, and

(3) organophilic membranes, which allow separation of one solvent from another. The separation is based on properties of the membrane material, dominated by polarity interactions but extending to size effects in nanoscale channels.

An overview of hydrophilic membrane materials for pervaporation is given in Table 1. Hydrophilic membranes have a water contact angle below 90° and are either made of polymeric or ceramic materials. They are successfully used for dehydration of solvents. Polymers are often based on polyvinyl alcohol (PVA) or polyimide (PI). Ceramic membranes can be made of silica or zirconia. Zeolites are also used;

zeolite A is used as a molecular sieve for pervaporation. Because of the well-defined structure of the zeolites, very high separation factors can be obtained with zeolite membranes. The separation is then based on size effects rather than polarity effects.

Hydrophobic membranes are summarized in Table 2. They have a contact angle between 90° and 120°. The typical polymer for hydrophobic pervaporation membranes is polydimethylsiloxane (PDMS). A typical application of hydrophobic pervaporation is the recovery of ethanol from a fermentation broth. Given the low concentrations of ethanol usually encountered, this requires a multistep approach.

Organophilic pervaporation is in an earlier stage of development because the separation is more challenging, and membranes for specific solvent separations are still scarce. Nevertheless, this is a highly promising membrane type in view of many applications, ranging from solvent recycling to solvent exchange in e.g., pharmaceutical production (Table 3).

A general problem for the stability of a membrane in pervaporation is the effect of the vacuum applied at the permeate side. The vacuum is needed to obtain a sufficient difference in partial pressure. In such conditions, the membrane is not swollen. In contrast, the membrane is in contact with the liquid feed mixture at the feed side, which causes swelling by uptake of solvent. The more flexible the polymeric chains are (e.g., linear polymers), the more the membrane swells at the feed side. This causes an asymmetric structure (swollen/unswollen), which causes mechanical stress that might lead to cracking. Swelling can be avoided by crosslinking of the polymer, but a balance is needed because crosslinking usually has a negative impact on fluxes.

Pervaporation Membrane Reactor

Bart Van der Bruggen

Department of Chemical Engineering, Process Engineering for Sustainable Systems (ProcESS), KU Leuven, Leuven, Belgium

A pervaporation membrane reactor (PMR) is an integrated reaction-separation system, in which one or more components from a reaction medium is selectively removed in order to increase the yield of the reaction (Van der Bruggen 2010). The component removed by pervaporation can be the product (type 1 PMR) or a by-product (type 2 PMR). This is schematically shown in Fig. 1 (Lipnizki et al. 1999).

Pervaporation membrane reactors can be used for bioconversions (type 1 PMR), such as the production of bioethanol and bio-butanol, and for the extraction of aroma components from a fermentation broth. Vane (2005) describes a pervaporation-bioreactor hybrid process for ethanol fermentation and further ethanol purification by dehydration (Fig. 2). A hydrophobic membrane is needed for ethanol extraction (polydimethylsiloxane membranes are typical for this application), followed by a hydrophilic membrane for obtaining a sufficient ethanol purity.

Another type of applications is in conversion reactions limited by the chemical equilibrium. According to the principle of Le Châtelier-Braun, selective removal of a by-product in the

Pervaporation Membrane Reactor,

Fig. 1 (a) Type R1 PMR (removal of reactor product) and (b) type R2 PMR (removal of by-product) (Lipnizki et al. 1999)

Pervaporation Membrane Reactor,
Fig. 2 Fermentation reactor coupled to hydrophobic pervaporation for ethanol extraction, with microfiltration

pretreatment, and dehydration with hydrophilic pervaporation (Adapted with permission from Vane (2005))

reaction shifts the reaction equilibrium to a higher product yield (type 2 PMR). A typical class of reactions in which this is applied is esterification:

The most simple esterification reaction is the reaction of ethanol with acetic acid to yield ethyl acetate and water. To enhance the yield of RCOOR' (ethyl acetate in the example), H₂O can be removed by a hydrophilic pervaporation membrane (Datta and Tsai 1995; Waldburger and Widmer 1996). The membrane to be used should be hydrophilic, often based on polyvinyl alcohol (PVA). Other materials include polyvinylalcohol/polyacrylonitrile (PVA/PAN), polyetherimide (PEI), and 4,4'-oxydiphenylene pyromellitimide (POPMI) (Van der Bruggen 2010). Ceramic pervaporation membranes have specific advantages (more robust and higher fluxes, although

more expensive). For this application, a pervaporation membrane reactor is an alternative to the more conventional (and more energy-consuming) reactive distillation.

Pervaporation membrane reactors can be even more integrated by using a catalytically active inorganic pervaporation membrane, which acts both as catalyst and separator. An acid zeolite, H-ZSM-5, was used in what was called an "active zeolite membrane reactor (AZMR)." Gao et al. (1996) and Tanaka et al. (2001) studied the esterification of acetic acid and alcohol, catalyzed by an exchange resin, using a zeolite A-PVA composite membrane, and a zeolite T membrane, respectively.

In spite of many applications already studied, transesterification reactions have not yet been extensively considered. Many esters are made using transesterification, because the milder conditions prevailing permit the reaction of

components containing additional functional groups. In alcoholysis, a complex alcohol is reacted with a methyl ester, forming a complex ester and methanol. These reactions are all equilibrium limited and are therefore candidates for use in a pervaporation membrane reactor. However, pervaporation membranes needed for this type of PMR should be organophilic, which is more challenging than classical solvent-water separations. Nevertheless, membranes for specific conditions (in particular with methanol selectivity) have been reported and can be used (Bhat and Pangarkar 2000; Ray et al. 1999). The use of pervaporation membrane reactors for transesterifications in comparison with reactive distillation has also been described by Brinkmann et al. (2009).

Pervaporation Separation Factor

Bart Van der Bruggen

Department of Chemical Engineering, Process Engineering for Sustainable Systems (ProcESS), KU Leuven, Leuven, Belgium

The selectivity of a pervaporation membrane in a given separation is usually calculated by the dimensionless separation factor α . For a binary mixture consisting of components *A* and *B*, the separation factor α is given by the following equation, in which y_A and y_B are the permeate compositions and x_A and x_B are the feed or retentate compositions:

$$\alpha_{AB} = \frac{y_A/y_B}{x_A/x_B}$$

These compositions can be described by means of mole fractions, mass fractions, or volume fractions (Mulder 1996).

The separation factor is chosen in such a way that its value is greater than unity and so that component *A* permeates preferentially. If $\alpha = 1$, no separation can be achieved (composition of the feed is identical to the feed composition).

The separation factor in pervaporation is calculated in the same way as the relative volatility in distillation applications (vapor-liquid equilibrium). Because the separation in pervaporation is not obtained by effects of volatilization, however, the selectivity in pervaporation is very different than for distillation for the same binary system. In the figure below, the McCabe-Thiele diagram showing the vapor-liquid equilibrium and the

Pervaporation

Separation Factor,

Fig. 1 Comparison between selectivity in pervaporation (*upper curve*) and distillation (*lower curve*) (Kujawski 2000)

feed-permeate relation in pervaporation for the ethanol-water system is shown (Kujawski 2000). The composition of the feed mixture is shown on the x-axis; the y-axis gives the composition of the vapor in equilibrium with the respective liquid (for distillation) or the composition of the permeate (for pervaporation). The pervaporation membrane in the figure is a hydrophilic membrane through which water is passing preferentially (for any concentration of water) and is enriched in the permeate. The highest separation factor can be observed at low water content. Thus, pervaporation is ideal for removal of water from the feed mixture at low concentrations of water, in the case of water-ethanol mixtures. In distillation, on the other hand, the more volatile ethanol is enriched in the vapor phase at high water concentrations (below the azeotropic point). With decreasing water in the feed, the vapor-liquid equilibrium shows azeotropic behavior, which means that the composition of vapor and liquid are identical; (ordinary) distillation cannot be used to cross the azeotropic point (Fig. 1).

An alternative way to quantify selectivity is by the dimensionless enrichment factor β , which is defined as the ratio of the fraction (molar or mass) of component A in the permeate to the fraction of component A in the feed:

$$\beta_A = \frac{y_A}{x_A}$$

Usually, there is a trade-off between the permeation flux and selectivity; i.e., when one factor increases, the other decreases. As both of them are important numbers in the separation process, a pervaporation separation index (PSI) can be defined as a measure of the separation ability of a membrane (Sommer and Melin 2005):

$$\text{PSI} = J_{\text{tot}} \alpha_{AB}$$

in which α_{AB} is the separation factor as defined above, and J_{tot} is the total flux through the membrane.

Compared to other membrane processes, such as *ultrafiltration* and *reverse osmosis*, pervaporation generally has low fluxes ($<10 \text{ kg/m}^2\text{h}$). Nevertheless, its selectivity can be extremely high, with α often exceeding 1,000 for separation of components with a large difference in polarity. This is not the case for more difficult separations such as ethanol-water, for which separation factors are typically below ten; the highest reported separation factors for ethanol-water separation are in the order of magnitude of 20 (Claes et al. 2011).

Flux and selectivity are strongly influenced by the specific characteristics of the components in the feed, the membrane, and the process-operating parameters. These factors include permeate pressure, process temperature, feed composition and concentration, feed turbulence, membrane thickness, *concentration polarization*, *temperature polarization*, and the membrane material.

Pervaporation Through Supported Liquid Membrane

Bart Van der Bruggen

Department of Chemical Engineering, Process Engineering for Sustainable Systems (ProcESS), KU Leuven, Leuven, Belgium

Supported liquid membrane pervaporation is a process for separating volatile organic compounds (VOCs) from their dilute aqueous solutions through a supported liquid membrane (Qin et al. 2002), often in a fermentation broth. It integrates simultaneous extraction of the VOCs from the aqueous solution with vacuum stripping of the

VOCs from the organic phase in one membrane module. The separation occurs by pervaporation, in which components selectively evaporate through a membrane. The membrane used in this case is a liquid membrane supported with a hydrophobic porous membrane (Matsumura and Kataoka 2004). The selectivity is thus determined by the choice of the liquid and its properties, and the selection of a proper liquid is a key factor for a successful separation. For example, oleyl alcohol was found to be the most suitable liquid for separating volatile products in ABE (acetone-butanol-ethanol) fermentation (Matsumura and Kataoka 2004). Oleyl alcohol is a preferred compound, since it is nontoxic to the microorganisms used in fermentation (Matsumura et al. 1992). The use of decanol (100 % pure) instead of oleyl alcohol (85 % pure) as the membrane solvent increased the flux and improved the stability without significant loss of performance up to about 70 h (Clement and Hossain 1997). Ionic liquids are a logical alternative in view of the stability of the membrane. Among the ionic liquids that have been considered are 1-ethenyl-3-ethyl-imidazolium hexafluorophosphate and tetrapropyl-ammonium tetracyanoborate (Izak et al. 2009) and tetracyanoborate and tris(pentafluoroethyl)trifluorophosphate (Heitmann et al. 2012), but the range of ionic liquids that can be used for this purpose is very wide. For example, Matsumoto et al. (2011) studied pervaporation of 1-butanol and isopropyl alcohol (IPA) through a poly vinyl chloride membrane (PVC) as the active layer and a porous hydrophobic polyvinylidene fluoride membrane as the support layer for a series of ionic liquids, including Aliquat 336, Cyphos 101, 102, and 104. It has been shown that the sorption step mainly affected the separation factor depending on the hydrophilicity of the ionic liquid (Matsumoto et al. 2009).

Applications of pervaporation through supported liquid membranes are in the field of bioconversions. For example, an oleyl alcohol supported liquid membrane was successfully applied to diacetyl fermentation by immobilized lactic acid bacteria by Ishii et al. (1995). Diacetyl productivity was about 10 g per m³ and per h, while the productivity during batch fermentation

was about 6 g per m³ and per h. The diacetyl yield from consumed glucose was about four times as large as that of batch fermentation. No fouling effects were encountered by using the actual fermentation broth: the flux of the permeate and the diacetyl separation factor for the pervaporation were maintained at almost constant levels during fermentation. The diacetyl concentration in the permeate, which was about 2 kg/m³, was found sufficiently high for commercial use.

A closely related process is vapor permeation through supported liquid membranes, which is applied in, for example, the separation of benzene and cyclohexane (Matsumoto et al. 2009). The difference is in the feed solution, which is a liquid for pervaporation and a vapor for vapor permeation. The choice between both processes is not a fundamental difference but usually depends on the feed mixture to be separated.

A general challenge for supported liquid membranes is their stability during application. For aqueous applications, it was shown that the loss of the ionic liquid from the supporting membrane towards the contacting aqueous phases is not negligible (Fortunato et al. 2004). Matsumoto et al. (2009), however, obtained a steady flux and separation factor and suggest that the membrane was extremely stable in the application that was considered.

Pervaporation-Assisted Reactor

Bart Van der Bruggen

Department of Chemical Engineering, Process Engineering for Sustainable Systems (ProcESS), KU Leuven, Leuven, Belgium

Synonyms

[Pervaporation membrane reactor](#)

Reactors coupled with membrane separation, such as pervaporation, can help to enhance the conversion of reactants for thermodynamically or kinetically limited reactions via selective removal of one or more product species from the reaction mixture (Benedict et al. 2006). A pervaporation-assisted reactor is more frequently denoted as a pervaporation membrane reactor, and both terms are usually considered as synonyms. Pervaporation-assisted reactors are always described as chemical reactors, in which a side

product is removed to shift the reaction equilibrium, and more specifically in the context of esterification reactions. In these reactors, a hydrophilic pervaporation membrane is used to selectively remove water, which is a non-desired side product of any esterification reaction (Datta and Tsai 1995). For example, ethanol and acetic acid react to ethyl acetate, with water as the side product to be removed. Esterification of acetic acid is also studied with other alcohols, with much attention for the reaction with butanol (Bitterlich et al. 1991). Other esterifications that have been studied include the reaction of propanol with propionic acid, the reaction of oleic acid with ethanol, the reaction of tartaric acid with ethanol, and the reaction of erucic acid with cetyl alcohol, among many others (Van der Bruggen 2010).

One important feature to optimize the design of pervaporation-assisted reactors (pervaporation membrane reactors) is the integration of catalysts into the membrane structure. Catalytically active pervaporation membranes are also called “bifunctional” membranes, i.e., catalytic and separative. The fixation of the catalyst to a membrane was proposed by Shah and Ritchie (2005), but the membranes originally proposed were microfiltration membranes (Van der Bruggen 2010). The membrane is then used both as catalyst and as a separator. Bernal et al. (2002) used a catalytically active inorganic pervaporation membrane for the same purpose, instead of a microfiltration membrane. An acid zeolite, H-ZSM-5, was used as a catalyst for esterification reactions (ethanol and acetic acid to produce ethyl acetate) in what was called an “active zeolite membrane reactor (AZMR).” De la Iglesia et al. (2006) followed the same approach and synthesized two-layered mordenite-ZSM-5 membranes for the same esterification reaction. Using a two-layered membrane, the catalytic activity and the hydrophilicity necessary to obtain a high flux are combined in a single structure.

Going beyond the classical esterification reactor, a pervaporation-assisted reactor for transesterification is an interesting but challenging extension. In a transesterification reaction, the side product is not water, but methanol; this implies that methanol is to be separated from the

reaction mixture. This is a much more difficult separation to achieve with regular pervaporation membranes. A new generation of organophilic membranes is appearing, which is thought to stimulate a wider scope of applications of pervaporation-assisted reactors/pervaporation membrane reactors, also for non-hydrophilic pervaporation separations.

A possible application of non-esterification pervaporation membrane reactors is the dehydration reaction of butanediol to form tetrahydrofuran (THF), catalyzed by $\text{H}_3\text{PW}_{12}\text{O}_{40}$ (Liu and Li 2002). Numerous other reactions are of potential interest for enhancement in a pervaporation-assisted reactor. Several are described in the literature; for an overview, the reader is referred to Van der Bruggen (2010). The requirements are as follows: (a) it concerns an equilibrium reaction and (b) the by-product formed in the reaction can be selectively removed by a pervaporation membrane.

Pervaporation-Based Hybrid System

► Pervaporation Hybrid System

Petrochemical Industry and Membrane Operations

Paola Bernardo

Institute on Membrane Technology, National Research Council of Italy, ITM–CNR, Rende, Italy

Petrochemical Industry includes different processes which, by means of chemical conversion and physical separations, produce a range of products, such as light olefins and aromatics, from the petroleum. Stringent environmental standards were important drivers for membrane implementation in the petrochemical/refinery processing, in a scenario of declining natural resources, for environmental and economic sustainability (Bernardo and Drioli 2010). Membrane systems can replace or can be integrated with conventional separation techniques (e.g., distillation, extraction, absorption, and adsorption), owing to modularity, low footprint, low energy intensity, no moving parts, and no need for solvents.

Polymeric membranes are available to recover valuable products like hydrogen and light hydrocarbons (ethylene, propylene and LPG) from refinery off-gas streams, or to produce nitrogen for inerting tanks. Hydrogen recovery from refinery tail gases had a rapid growth, owing to an

increased demand of hydrogen to desulfurize feedstocks and liquid heavy fractions. An increasing number of vapor/gas membrane systems are installed for gasoline vapor recovery at truck loading and retail gasoline stations or for the recovery of olefins and their recycle in the polyolefin production, thus reducing air pollution and achieving fuel savings (Baker et al. 1998). Plasticization-resistant perfluorinated membranes were specifically developed for these applications (Pinnau et al. 2002).

Organic solvent nanofiltration had the first large-scale application in solvent recovery from the dewaxing in lube oils processing, reducing the amount of crude oil required to produce a given volume of lube base stock and the loss of dewaxing solvents (Bernardo and Drioli 2010). It is also applied to remove tar components in FCC feed (Vandezande et al. 2008). Pervaporation allows to dehydrate solvents without the use of any third substance and to split azeotropes (Wynn 2001) and could effectively separate aromatic/nonaromatic hydrocarbon mixtures, as in the production of cyclohexane, to remove the unreacted benzene and to recover pure cyclohexane (Ye et al. 2008).

Wastewater treatment is one of the most important applications of membranes in the petrochemical field, meeting the increasing water quality standards prior to discharge, although these applications present challenging effluent streams. Stricter effluent regulations and increasing need for reuse/recycling of treated water were important drivers for implementing the membrane bioreactor (MBR) system in the petrochemical and refining industries with economic and environmental benefits. The MBR, combining the traditional biological degradation with a low-pressure membrane filtration, is an intensified process, with low space requirements and low visual impact, allowing to recycle water and reduce effluent discharge. In refineries, the highly treated wastewater can be reused in the crude processing, as cooling tower makeup, as boiler feedwater, or for other utility purposes. Recently, different refineries in Saudi Arabia and in the Middle East began to sell the treated water for irrigation (Bernardo and Drioli 2010).

The largest waste stream generated in oil and gas industries, referred to as produced water, is brought to the surface with oil (Ahmadun et al. 2009). The water stress in regions with freshwater scarcity is a strong driver to reclaim the produced water as potable and usable for agriculture irrigation, or alternatively in enhanced oil recovery. In this way, the petroleum industry could become a producer of freshwater. Produced water is typically saline; thus, it can be processed by a pretreatment followed by MBR treatment and reverse osmosis (Bernardo and Drioli 2010).

Integrated membrane systems offer the possibility of redesigning the energy-intensive refining/petrochemical industry, as proposed in an ethylene production cycle by steam cracking (Bernardo et al. 2004). The integration of different membrane systems (microfiltration, gas separation, membrane contactors) has shown the potential to reduce exergy with respect to conventional separation methods. This strategy would allow to develop new process concepts, improving the material utilization by a separation/recycle approach, reducing at the same time chemicals, energy/utility consumption, and waste stream production in refineries for clean fuel production and other important petrochemical productions.

Phasing Methods in Crystal Structure Determination

Rocco Caliendo

Institute of Crystallography, CNR, Bari, Italy

Crystals obtained by membrane crystallization processes can be structurally investigated by means of Crystallography. The crystal structure can be determined by means of a diffraction experiment, which is outlined in Fig. 1. A crystal sample is irradiated by an intense X-ray beam, and the intensity of each reflection $\mathbf{h}$, representing a given direction of the scattered X-ray beam, is collected by an area detector. The intensity $I_{\mathbf{h}}$ is proportional to the modulus of the structure factor $F_{\mathbf{h}}$, which is a complex quantity, representing the response of the crystal system to the X-ray perturbation. However, to rebuild the image of the crystallized compound and then determine its structure, the phases $\varphi_{\mathbf{h}}$ of the structure factors are also necessary. In fact they depend on the positions of the atoms in the crystal cell. Thus, the phase problem consists in determining the phase of structure factors from their moduli. It can be solved by different computational methods, called “phasing methods”.

They can be classified as in Fig. 2. If measured intensities are the only information available, they are called *ab initio* methods; the most popular ones are direct or Patterson methods. The first works in the reciprocal space and makes use of

Phasing Methods in Crystal Structure Determination,

Fig. 1 Schematic view of a diffraction experiment

Phasing Methods in Crystal Structure Determination,

Fig. 2 Classification of existing phasing methods

the quantities $F_{\mathbf{h}}$ and $\varphi_{\mathbf{h}}$; the latter operates in the direct space and makes use of the electron density maps $\rho(\mathbf{r})$. Direct and reciprocal spaces are dual spaces, and their related quantities are connected by the relations:

$$F_{\mathbf{h}} = T[\rho(\mathbf{r})] \quad (1)$$

$$\rho(\mathbf{r}) = T^{-1}[\mathbf{F}_{\mathbf{h}}] \quad (2)$$

where T and T^{-1} denote the Fourier transform and anti-transform, respectively (Giacovazzo 1998). More recently, dual-space approaches have been developed, which work in both direct and reciprocal space.

Direct Methods

Direct methods allow extracting phase values directly from the observed structure factors moduli. They use a probabilistic approach (Hauptman 1975; Giacovazzo 1980) and are based on two general assumptions: the positivity of the electron density map and its atomicity, i.e., the fact that the electron density is not evenly distributed in the cell but is concentrated at the atomic positions.

Patterson Deconvolution Methods

The moduli of the structure factors contain information on the interatomic vectors of the crystal structure. This information can be made visible by calculating the Patterson map, through equation $P(\mathbf{u}) = T[F_{\mathbf{h}}^2]$. An ideal Patterson map can be interpreted as formed by the superposition of N images of a structure of N atoms, each shifted relative to the other by an interatomic vector (Buerger 1959). The recovery of a single image from the set of overlapping images can be accomplished by deconvolving the Patterson map, through vector superposition procedures (Caliandro et al. 2007).

Dual-Space Approaches

They are based on the assumption that a crystal structure is confined in a small region of the unit cell with high positive density; the rest of the map may be represented by large plateaus of negligible density. Constraints are imposed in each space: in direct space, specific modifications are applied to the electron density map, and in reciprocal space, calculated phase values are associated with

observed structure factor amplitudes to produce a new map. They are the charge flipping (Oszlányi and Sütö 2008) and *Vive La Différence* (Burla et al. 2010a, b) methods.

Non-Ab Initio Phasing

If instead additional information is available, the phasing methods are not ab initio. They are called isomorphous replacement when a derivative crystal containing heavy atoms is used or anomalous dispersion when the resonant scattering of some atoms of the structure is used (Giacovazzo 1998). If instead the approximate structural model is a priori known, the approach consists in searching for the best position and configuration of the structural model within the unit cell, driven by the agreement with experimental data. In case of small molecules, a global optimization search is used (Kirkpatrick 1984), and the uncertainty about the structural model is parameterized so that a flexible model is used within the search procedure (Favre-Nicolin and Černý 2002; Altomare et al. 2003). In case of macromolecules, the configuration of the structural model is not changed, and special vector search procedures, called molecular replacement, are used to place it in the unit cell (Rossman 1972).

Phenol Degradation Using Membrane Reactor

Raffaele Molinari

Dipartimento di Ingegneria per l’Ambiente e il Territorio e Ingegneria Chimica (DIATIC),
Università della Calabria, Rende, Italy

Phenol is one of major pollutants in industrial wastewater with high remediation priority. In the following a summary of some studies concerning phenol degradation in membrane reactors is reported.

Wastewater from coal gasification has poor biodegradability and high toxicity. A laboratory-scale anaerobic-anoxic-oxic membrane reactor (AAO-MBR) system was developed to investigate the treatment ability of coal gasification wastewater by Wang et al. (2012). The removal capacity of each pollutants used in this system was determined at different hydraulic residence times (HRT) and mixed liquor recycle ratios (R). The experimental results showed that this system could effectively deal with COD and phenol removal and remained in a stable level when the operational parameters were altered, while the nitrification was sensitive to operational conditions. The best performance was obtained at

HRT of 48 h and R of 3. The maximum removal efficiencies of COD, $\text{NH}_4^+\text{-N}$, and phenols were 97.4 %, 92.8 %, and 99.7 %, with final concentrations in the effluent of 71 mg/L, 9.6 mg/L, and 3 mg/L, respectively. Organic degradation and transformation were analyzed by GC/MS (gas chromatography/mass spectrometry), and it was found that anaerobic process played an important role in degradation of refractory compounds.

The effect of salt concentration on the performance of a membrane bioreactor (MBR) for treating an olefin plant wastewater was investigated by Sadeghi et al. (2012). For this purpose, a lab-scale submerged MBR with a flat-sheet ultrafiltration membrane was used for treatment of synthetic wastewater according to oxidation and neutralization unit of olefin plant. The synthetic wastewater was adjusted to have 500 mg/L chemical oxygen demand (COD). Trials on different concentrations of sodium sulfate (Na_2SO_4) (020–000 ppm) in the feed were carried out under aerobic conditions in the MBR. The results showed that increasing the salt concentrations causes an increase in the effluent COD, phenol, and oil concentrations. These results are due to reduction of the membrane filtration efficiency and also decline in the microbial activity. But in all the trials, the effluent COD and oil concentration were well within the local discharge limit of 100 and 10 mg/L, respectively. These results indicate that the MBR system is highly efficient for treating the olefin plant wastewater, and although high salt concentrations decreased organic contaminant removal rates in the MBR, the effluent still met the discharge limits for treating the olefin plant wastewater.

In municipal wastewater treatment plant (WWTP) effluents, the problem due to the presence of micropollutants in wastewater which may be able to disrupt the endocrine system of some organisms has been faced by Abargues et al. (2012). The fate of the alkylphenols (APs) (4-(tert-octyl) phenol, t-nonylphenol, and 4-p-nonylphenol) and the hormones (estrone, 17 beta-estradiol, and 17 alpha-ethinylestradiol) in a submerged anaerobic membrane bioreactor (SAMBR) pilot plant and in a conventional-activated sludge wastewater treatment plant

(CTP) has been compared. The obtained results were also compared with those obtained in a previous study carried out in an aerobic MBR pilot plant. The results showed that the AP soluble concentrations in the SAMBR effluent were always significantly higher than those in the CTP. Moreover, the analyses of the suspended fraction revealed that the AP concentrations in the SAMBR reactor were usually higher than in the CTP reactor, indicating that under anaerobic conditions, the APs were accumulated in the digested sludge. The aerobic conditions maintained both in the CTP system and in the aerobic MBR that favored the AP and hormone degradation and gave rise to lower concentrations in the effluent and in the reactor of these systems. Furthermore, the results also indicated that the degradation of APs under aerobic conditions was enhanced working at high solid retention time (SRT) and hydraulic retention time (HRT) values.

Direct coupling of separation and photocatalytic degradation by using photocatalytic membrane is an attractive way to solve problems like membrane fouling by adsorbed organic macromolecules or elimination of small organic molecules which cannot be efficiently stopped by a membrane. A simple and robust synthesis route to a photocatalytically active titania membrane was developed from a commercial TiO_2 hydrosol and commercial alumina supports by Djafer et al. (2010). Reproducible defect-free layers with a thickness of about 3 μm were prepared. The membrane performance in term of separation and photocatalytic activity was investigated. The pure water permeance was $150 \text{ L h}^{-1} \text{ m}^{-2} \text{ bar}^{-1}$ and the measured molecular weight cut-off was around 50 kDa corresponding to an ultrafiltration membrane. The photocatalytic efficiency was tested by photooxidation under UV irradiation of a reference organic dye (methylene blue) for comparison with reference TiO_2 photocatalysts and also with phenol as typical organic pollutant in water. The measured values of quantity of destroyed organic molecules per units of time and of membrane surface area are in the range $0.8\text{--}3.8 \times 10^{-8} \text{ mol s}^{-1} \text{ m}^{-2}$.

Phenol decomposition was carried out under UV irradiation in a recycle batch photocatalytic membrane reactor (PMR) by Yang et al. (2011).

To overcome the problem of post-recovery of the catalyst particles after water treatment, surface modification of polypropylene macroporous membrane was performed with the technique of photoinduced reversible addition-fragmentation chain transfer grafting polymerization of acrylic acid. TiO_2 photocatalysts were introduced into the acrylic acid-grafted membrane surface. In the tests on the PMR, the normalized membrane flux reached 1.7 times that of the unmodified membrane for the poly(acrylic acid) (PAAc)-modified membrane. Introducing TiO_2 photocatalysts into the membrane surface reduced slightly the normalized membrane flux. For the PMR with a grafting degree of 12.9 % (wt) of PAAc on the membrane surface, the corresponding decomposition percentage was 32.5 % after 6 h UV light irradiation.

The role of membrane in phenol degradation in high-phenol-fed MBR (membrane bioreactor) was explored by Ahn et al. (2011). Phenol elimination in high-phenol-fed MBRs resulted in complete mineralization, and the high-phenol-fed MBR exhibited greater biomass-specific phenol removal rates (0.4–1.5 mg phenol/(mg VSS.d)) than the low-phenol-fed MBR. In the high-phenol-fed MBR, filamentous non-settling microbes were more abundant than in the low-phenol-fed MBR. Batch experiment, high-acclimated, and non-settling microbes were separately collected from the high-phenol-acclimated bioreactor, and their specific phenol degradation was determined at 5.1 mg phenol/(mg VSS.d). The greater specific phenol degradation rate of the non-settling microbes than the observed phenol elimination rate in the high-phenol-fed MBR indicated that the high-phenol-acclimated and non-settling microbes had greater degradation activity than the rest of sludge microbes in the bioreactor. According to these findings, the role of membrane in the high-phenol-fed MBR was identified as the containment of non-settling and biodegradative microbes in bioreactor, and in turn, the membrane-driven increase of non-settling phenol degrading microbes enhanced phenol elimination in the high-phenol-fed MBR.

A novel process to biodegrade phenol present in an acidic (1 M HCl) and salty (5 % w/w NaCl)

synthetically concocted wastewater was studied by Livingston (1993). The process utilized a membrane bioreactor, in which the phenol present in the wastewater was separated from the inorganic components by means of a silicone rubber membrane. Transfer of the phenol from the wastewater into a biological growth medium allowed biodegradation to proceed under controlled conditions which were unaffected by the presence of inorganic species in the synthetic wastewater. At a wastewater flow rate of 18 mL h^{-1} (contact time 6 h), 98.5 % of phenol present in the wastewater at an inlet concentration of $1,000 \text{ mg L}^{-1}$ was degraded; at a contact time of 1.9 h, 65 % of the phenol was degraded. Phenol degradation was accompanied by growth of a biofilm on the membrane tubes and by conversion of approximately 80 % of the carbon entering the system to CO_2 carbon. Analysis of the transport of phenol across the membrane revealed that the major resistance to mass transfer derived from the diffusion of phenol across the silicone rubber membrane. A mathematical model was used to describe the transfer of phenol across the membrane and the subsequent diffusion and reaction of phenol in the biofilm attached to the membrane tube. This analysis showed that (a) the attached biofilm significantly lowers the mass transfer driving force for phenol across the membrane, and (b) oxygen concentration limits the phenol degradation rate in the biofilm. These conclusions from the model are consistent with the experimental results.

The effect of adaptation of mixed culture in the phenol biodegradation was studied by Marrot et al. (2006). The degradation experiments were carried out at different phenol concentrations from 0.5 to 3 g L^{-1} . Biological treatment showed to be economical and practical leading to a complete removal of phenol. High concentrations of phenol were inhibitory for growth, so it was for the rates of substrate utilization that were greater at low initial concentrations. Haldane kinetics model for single substrate was used to obtain maximum specific growth rates ($\mu_m = 0.438 \text{ h}^{-1}$), half saturation ($K = 29.54 \text{ mg L}^{-1}$), and substrate inhibition constant ($K_{-i} = 72.45 \text{ mg L}^{-1}$). These results were in agreement with those reported in the literature for phenol removal abilities in different systems,

although the concentration in phenol was significant, and the Haldane model was acceptable.

Phenol Production by Membrane Reactor

Raffaele Molinari

Dipartimento di Ingegneria per l'Ambiente e il Territorio e Ingegneria Chimica (DIATIC),
Università della Calabria, Rende, Italy

The great interest in the oxidation reaction of benzene to phenol is linked to some disadvantages of the cumene process, such as environmental impact,

production of an explosive intermediate and the fact that this is a multistep process that involves a low yield of phenol and a high capital investment. Moreover, the high acetone production as a coproduct, which results in an oversupply in the market, is another drawback. Various studies concerning a new approach based on a one-step and acetone-free method for phenol production have been reviewed by Molinari and Poerio (2010). Particular attention was devoted to phenol production processes using various configurations of membrane reactors (MRs) and a photocatalytic membrane reactor (PMR). In particular, the biphasic MR allowed to achieving high selectivity values (97–98 %). The various methods have been classified according to oxidant type such as N_2O , O_2 , and H_2O_2 . All of them indicated that direct oxidation of benzene to phenol is a difficult task and further efforts are needed to search and to replace the three-step traditional process with a process of direct oxidation to convert benzene in phenol.

Phenol production through the direct hydroxylation of benzene with hydrogen peroxide using a catalytic membrane reactor was studied by Molinari et al. (2006). The reaction was carried out in a biphasic system separated by a membrane. This new system showed a high selectivity to phenol, minimizing its overoxidation in overoxygenated by-products. The effect of various reaction parameters such as the addition of hydrogen peroxide mode, amount of hydrogen peroxide, type of membrane, type of catalyst, and organic acid was investigated. The results showed that iron(II) sulfate as the catalyst, 18 mmol of hydrogen peroxide pumped for 4 h in the aqueous phase as oxidant feeding, acetic acid and polypropylene hydrophobic porous support gave the best system performance in terms of produced phenol (17.42 mmol), selectivity to phenol (99.94 %), benzene conversion to phenol (1.20 %), and conversion of hydrogen peroxide to phenol (96.78 %).

Use of vanadium based catalysts and product recovery in benzene hydroxylation to phenol was studied in a two-phase membrane reactor by Molinari et al. (2012). Benzene permeates, through the hydrophobic polypropylene membrane, in the aqueous phase containing the

catalyst while phenol permeates back accumulating in the organic phase. The following fundamental aspects have been studied: dose of hydrogen peroxide, initial oxidation states of vanadium catalysts, duration of catalytic tests, and lifetime of the membrane in terms of physical and chemical resistance. It was observed that by feeding the oxidant by a micro pump, working in the “bulk tube” mode, phenol yield, final phenol concentration in the organic phase, phenol turnover number, and system productivity increased, and no tar was formed. Initial oxidation state of vanadium catalysts influenced system performance: indeed improved results in terms of yield (35.2 % vs. 25.1 %), conversion of hydrogen peroxide to phenol (36.6 % vs. 25.9 %), and productivity ($0.97 \text{ g g(cat)}^{-1} \text{ h}^{-1}$ vs. $0.78 \text{ g g(cat)}^{-1} \text{ h}^{-1}$) were obtained by using vanadium(III) chloride compared to vanadium(IV) acetyl acetonate. Higher phenol extraction/recovery in the organic phase (61.1 % vs. 46.3 %) and then higher selectivity (97.5 % vs. 92.8 %) were obtained by increasing test duration from 270 to 510 min. A weak membrane resistance was observed after 246 h of consecutive catalytic runs on the same membrane piece, showing degradation of the membrane material (polypropylene) caused by the OH radical generated in the reacting mixture.

The one-step hydroxylation of benzene to phenol with oxygen and hydrogen was studied by Shu et al. (2009). It is a promising process, but there are severe challenges associated with the low phenol production. It was shown that the reaction can be greatly promoted by the simultaneous use of a dense palladium membrane as a catalyst and as a hydrogen distributor. This reaction concept with palladium membranes was tested under different reaction conditions, but it was found that the palladium membranes were almost inert for both the target reaction and the benzene combustion. The authors summarized and compared their results with those reported in the literature investigating the effects of the membrane preparation method and the combustion of hydrogen and benzene. The hypotheses on the mechanism and feasibility of the membrane concept are also given.

A simple, low-cost design of glass capillary microreactor for the catalytic oxidation of benzene to phenol at ambient conditions was studied

by Basheer (2013). Polyvinylchloride-nanofiber-membrane-supported titania nanoparticles (TiO_2 -PVC) as catalyst was used by producing in situ hydroxyl radicals as oxidant. The reaction was monitored by gas chromatography–mass spectrometry (GC-MS). The reaction conditions were optimized and the performance of the microreactor was then compared with the conventional laboratory scale reaction which used hydrogen peroxide as oxidant. The microreactor gave a better yield of 14 % for phenol compared to 0.14 % in the conventional laboratory scale reaction. Reaction conditions such as reaction time, reaction pH, and applied potential were optimized. With optimized reaction conditions selectivity higher than 37 % and conversion of benzene higher than 88 % were obtained.

The study of a new reactor design with separate membranes for distributed dosage of hydrogen and oxygen, respectively, into microstructured reaction channels for the direct conversion of benzene to phenol in the gas phase in a palladium membrane reactor has been investigated by Bortolotto and Dittmeyer (2010). The highest phenol selectivity so far obtained on a palladium-coated PdCu foil at 423 K was 9.6 % with carbon dioxide being the dominant product.

Phenol Recovery Using Membrane Contactor

Raffaele Molinari

Dipartimento di Ingegneria per l'Ambiente e il Territorio e Ingegneria Chimica (DIATIC),
Università della Calabria, Rende, Italy

Phenol recovery from different aqueous solutions (industrial wastewater and process water) is of wide interest from environmental and industrial point of view. Among the various recovery processes, some of the involving membranes are described in the following.

The recovery of phenol from aqueous solutions with CYANEX (R) 923 was studied by Cichy et al. (2001). Classical dispersive extraction and three membrane extraction-stripping systems (bulk liquid membranes, three-phase hollow-fiber contactor, and two hollow-fiber module setup) were used. It was found that CYANEX (R) 923 was a convenient carrier for recovery of phenol from aqueous streams in extraction-stripping membrane processes. The problem of emulsion formation, so important in dispersive extraction, was avoided. Both mass-transfer experiments in different membrane systems and measurement of the dynamic interfacial tension demonstrated the importance of the interfacial phenomena occurring in the stripping stage. A blocking of this interface was observed that resulted in a decrease of phenol mass transfer.

Pertraction of dimethylcyclopropanecarboxylic acid (DMCCA) and phenol in a new hollow-fiber (HF) contactor of three liquid phases with distributed U-shaped bundles of microporous HF was studied by Schlosser et al. (2002). Trioctylamine (TOA), Hostarex A327, and Cyanex 47 1 X have been used as carriers. The performance of this contactor is similar to other HF contactors. Its advantage is that both bundles of fibers can elongate without deformation of fibers and maldistribution of fibers in the bundles. Pulsation of the membrane phase increases the transport rate by 35–61 %, and it reaches a plateau value at the pulsation velocity of about $1.1 \text{ mm} \cdot \text{s}^{-1}$.

With increasing velocity of the feed in the fiber lumen, the value of the overall mass-transfer coefficient increases, but soon a steady value is approached at the velocity of about $5.5 \text{ cm} \cdot \text{s}^{-1}$. The diffusion resistances in a series model do not describe the pertraction of DMCCA well. The suggested new diffusion-reaction model, considering the resistance based on the kinetics of the stripping reaction, fits experimental data well. Not only the rate of the acid-carrier complex decomposition but also that of the DMCCA dimer decomposition has to be considered. The estimated values of the apparent reaction rate constant were for the membrane with TOA $1.91 \cdot 10^{-6} \text{ m} \cdot \text{s}^{-1}$ and for pure *n*-alkanes $5.78 \cdot 10^{-6} \text{ m} \cdot \text{s}^{-1}$. The kinetic resistance on the stripping interface represents 20–60 % of the overall mass-transfer resistance, and its value is comparable to the diffusion resistance of both walls.

Application of membrane techniques (pervaporation and membrane-based solvent extraction) and adsorption to the removal of phenol from solutions modeling wastewater from phenol production by cumene oxidation process was investigated by Kujawski et al. (2004). The transport and separation properties of composite membranes PEBA, PERVAP 1060, and PERVAP 1070 in pervaporation of water-phenol mixtures were determined. It was found that the best removal efficiency of phenol was obtained using the PEBA membrane. MTBE, cumene, and the mixture of hydrocarbons were applied in the membrane-based phenol extraction. Extra-flow contactor with Celgard X-30 polypropylene hollow-fiber porous membranes was used in the experiments. MTBE was found the most efficient extractant. Adsorption of phenol on the different Amberlite resins was also investigated. Among the Amberlite resins of various grades used, the Amberlite XAD-4 had the best properties in the phenol removal from the aqueous solutions. It was shown that regeneration of the adsorbent bed could be effectively performed with sodium hydroxide solution.

The extraction and stripping of phenol using a solution of tributyl phosphate in kerosene in a hydrophobic polypropylene hollow-fiber membrane contactor was studied by Shen

et al. (2009). The effect of the aqueous and the organic phase flow rates on the overall mass-transfer coefficient for both extraction and stripping steps was investigated. Experimental values of the overall mass-transfer coefficient were determined and compared with predicted values from the resistance in series model. Results showed that the overall mass-transfer coefficients for extraction were about one order of magnitude greater than those measured during the stripping process. The experimental values were in good agreement with the predicted values for the extraction module. However, the predicted values were slightly overestimated for the stripping module. The individual mass-transfer resistances were analyzed, and the rate-controlling steps of mass transfer were also identified in both extraction and stripping modules. The major resistance in extraction and stripping was in the aqueous phase and in the membrane phase, respectively.

The removal of phenols from wastewater has been investigated under various operational conditions using hydrophobic hollow-fiber membrane contactors (Shen et al. 2012). Experimental overall mass-transfer coefficients were obtained in both handmade and Liqui-Cel™ modules. Model predictions based on a resistance in series model with solvent-filled membrane pores matched well with experimental values for tributyl phosphate/Shellsol extraction systems. However, the predictions were in poor agreement with experimental data obtained when 50 % pentanol/xylene was used to treat industrial wastewater in the handmade module. Further analysis showed that the operational pressure on the aqueous side and the breakthrough pressure for the two solvents probably influenced the position of the interface within the membrane pores. This change in wetting patterns resulted in significant differences in mass transfer and solute recovery which can be accounted for by adjusting the position of the interface within the membrane fiber.

Phenol Separation on PV Membrane Reactor

Raffaele Molinari

Dipartimento di Ingegneria per l'Ambiente e il Territorio e Ingegneria Chimica (DIATIC),
Università della Calabria, Rende, Italy

Phenol separation from different aqueous and nonaqueous solutions (industrial wastewater and process water) using pervaporation (PV) membranes is of wide interest from environmental and industrial point of view. In the following, applications of these membranes are described.

A general review on different membrane processes and membrane reactors in petrochemical industry, such as olefin/paraffin separation processes, light solvent separation, solvent dewaxing, phenol and aromatic recovery, dehydrogenation, oxidative coupling of methane, and steam reforming of methane were discussed in detail by Ravanchi et al. (2009). Besides, separation using polymer-inorganic nanocomposite membranes and wastewater treatment using membrane bioreactors are reported. The available technologies for the abatement of phenol from water and gaseous streams were briefly reviewed, and the recent advancements summarized by Busca et al. (2008). In this work separation technologies, such as distillation, liquid-liquid extraction with

different solvents, adsorption over activated carbons and polymeric and inorganic adsorbents, membrane pervaporation, and membrane-solvent extraction, are discussed. Destruction technologies such as non-catalytic, supercritical, and catalytic wet air oxidation; ozonation; non-catalytic, catalytic, and enzymatic peroxide wet oxidation; electrochemical and photocatalytic oxidation; supercritical wet gasification; destruction with electron discharges; as well as biochemical treatments are also considered. In particular, for the abatement of phenol from gases, condensation, absorption in liquids, adsorption on solids, membrane separation, and thermal, catalytic, photocatalytic, and biological oxidation are also described and the experimental conditions and performances of the different techniques compared.

Application of membrane techniques (pervaporation and membrane-based solvent extraction) and adsorption to the removal of phenol from solutions modeling wastewater from phenol production by cumene oxidation process was investigated by Kujawski et al. (2004a). The transport and separation properties of composite membranes PEBA, PERVAP 1060, and PERVAP 1070 in pervaporation of water-phenol mixtures were determined. It was found that the best removal efficiency of phenol was obtained using the PEBA membrane. MTBE, cumene, and the mixture of hydrocarbons were applied in the membrane-based phenol extraction. Extra-Flow contactor with Celgard X-30 polypropylene hollow-fiber porous membranes was used in the experiments. MTBE was found the most efficient extractant. Adsorption of phenol on the different Amberlite resins was also investigated. Among the Amberlite resins of various grades used, the Amberlite XAD-4 had the best properties in the phenol removal from the aqueous solutions. It was shown that regeneration of the adsorbent bed could be effectively performed with sodium hydroxide solution.

Application of pervaporation and adsorption to the removal of phenol from solutions modeling wastewater from phenol production with cumene oxidation process was investigated by Kujawski et al. (2004b). The transport and separation

properties of composite membranes PEBA, PERVAP 1060, and PERVAP 1070 in pervaporation of water-acetone, water-phenol, and water-phenol-acetone mixtures were determined. It was found that all membranes were selective toward phenol. The PEBA membrane showed the best selectivity. However, this membrane is not actually available on the commercial scale. Thus, in the practical applications, PERVAP-1060 and PERVAP-1070 could be used. Adsorption of phenol on the different Amberlite resins was also investigated. Among the Amberlite resins of various grades used, the Amberlite XAD-4 had the best properties in decontamination of aqueous phenol solutions. It was shown that regeneration of the adsorbent bed could be effectively performed with sodium hydroxide solution.

The separation of a phenol-water mixture using a polyurethane membrane by a pervaporation method was investigated by Hoshi et al. (1997). Polyurethane was selected as a membrane material because its affinity for phenol was considered to be high and was prepared by the polyaddition of 1,6-diisocyanatohexane and polytetramethyleneglycol. The polyurethane layer was sandwiched with a porous polypropylene membrane (Celgard[®] 2500). Pervaporation measurements were carried out under vacuum on the permeate side, and the permeate vapor was collected with a liquid nitrogen trap. The phenol concentration in the permeate solution increased from 0 to 65 wt.% with increasing feed concentration of phenol from 0 to 7 wt.%. The total flux also increased up to $930 \text{ g}\cdot\text{m}^{-2}\cdot\text{h}^{-1}$ with increasing phenol partial flux. In the sorption measurement at 60 °C, the concentration of phenol in the membrane was 68 wt.%, which was higher than that of the permeate solution.

The effect of the methylene group length in poly(alkylene glycols) on permselectivity and solubility of phenol was studied by Hoshi et al. (2000) in dilute aqueous solution through polyurethane membranes by pervaporation. The poly(alkylene glycols) were obtained by polycondensation of 1,6-hexanediol, 1,8-octanediol, and 1,10-decanediol with a sulfuric acid catalyst. Polyethyleneglycol and polytetramethyleneglycol were commercially available. Progress of the polymerization in the poly(alkylene glycols) was

confirmed by FTIR, ^1H -NMR analysis, and size-exclusion chromatography (SEC) measurements. The polyurethanes were obtained by polyaddition reaction of 1,6-hexamethylenediisocyanate and the poly(alkylene glycol) and were confirmed by FTIR analysis and SEC measurements. The phenol concentration in a permeate liquid increased from 25.1 to 36.2 wt.%, and the phenol partial flux also increased from 49.3 to 68.9 $\text{g}\cdot\text{m}^{-2}\cdot\text{h}^{-1}$ with increasing the methylene group length in the poly(alkylene glycols), whereas the water partial flux slightly decreased. As a result of sorption measurements, the change in the degree of swelling was small, and the phenol concentration in the membrane increased from 42.1 to 70.8 wt.%. The increase in the methylene group length of the poly(alkylene glycols) should contribute to an increase in the hydrophobicity of the polyurethane so that the solubility of phenol to the membrane should increase. The phenol concentration in the permeate liquid and the phenol partial flux increased with an increase in the methylene group length of the poly(alkylene glycols) due to the increase in the phenol solubility for the polyurethane membranes.

Phenolic Compound

Beatriz Mello

UFSCar, Federal University of Sao Carlos, Buri, SP, Brazil

Phenolic compounds are a chemical class consisting by at least one aromatic ring (C6) bearing one or more hydroxyl groups. The hydrogen of the phenolic hydroxyl groups is labile thanks to the aromatic ring, which is responsible for the weak acid characteristic of phenols (Wermerris and Nicholson 2007). They are found in the natural world, being one of the most important groups occurring in the plant kingdom where they are the most abundant secondary metabolites in plants – usually found as esters or glycosides and not as free compounds. They are responsible for several functional activities in plant's life cycle including defense, attractants for pollinators, and protection against ultraviolet light (Jaganath and Crozier 2010). These characteristics explain their wide use commercially as flavoring agents, natural drugs, antioxidants, etc., acting as natural additives.

Phenol ($\text{C}_6\text{H}_5\text{OH}$) is the simplest compound of the class (also called carboic acid), and its structure is represented in Fig. 1. Polyphenols are compounds that have more than one hydroxyl group attached to one or more benzene rings.

It is possible to divide the phenols in several different groups according to the number of carbons in conjunction with the structure of the basic phenolic skeleton – simple phenols, phenolic acids, coumarins, phenylpropanoids, flavonoids, antocyanins, catechins, terpenoids, to highly polymerized compounds, such as condensed tannins. Their molecular weight is in the range of

Phenolic Compound,

Fig. 1 Basic structure of a phenol

90–350 g/mol. Flavonoids constitute the most important polyphenolic class, with more than 500 compounds already described.

These compounds are reported to exhibit anticarcinogenic, antiinflammatory, antioxidant, and antimicrobial activities, among others. Several studies were carried out in order to correlate the consumption of foods with high concentrations of polyphenols and the reduced risk of degenerative diseases, mostly with very positive results. For example, they can prevent neurodegeneration by trapping radicals, working as a preventive action. So, phenolic compounds presented a potential protective role through ingestion of fruits and vegetables, working against oxidative damage diseases (coronary heart disease, stroke, and cancers) (Jaganath and Crozier 2010).

Their antioxidant activities and the possibility of use in processed foods as a natural antioxidant are the explanation for the increased interest in phenolic acids. Their antioxidant properties come from their redox potential, which can act as free radical scavengers, hydrogen donors, metal chelators, and singlet oxygen quenchers. The effectiveness in food depends on not only the number and location of hydroxyl groups but also on factors such as physical location, interaction with other food components, environmental conditions (e.g., pH), and the degree of glycosylation – aglycons of quercetin and myricetin are more active than their glycosides (Marchand 2002). The most well-known physiological phenolic antioxidant is vitamin E.

Antimicrobial activity of phenolic compounds is related to the principle of inactivation of cell enzymes, what explains the different activities between Gram-negative and Gram-positive species once they have variations in their cell structures. The antimicrobial effect related with phenolic compounds contents in several natural products, as olive (Pereira et al. 2007), wine (Cueva et al. 2012), mushroom (Barros et al. 2007), propolis extracts (Hendi et al. 2011), and green tea (Kristanti and Punbusayakul 2009).

As every natural product, phenolic compounds have a great utilization potential in several processes in order to aggregate their main properties. It is important to know their action mechanisms

and utilization forms to produce better products with functional properties.

The use of membrane operations to separate, purify, and produce phenolic compounds from natural sources is very attractive due to the clean, safe, and low energy input of the technology

Phosphate Removal from Water and Wastewater by Membrane Operations

Aamer Ali

Department of Environmental and Chemical Engineering, University of Calabria, Rende, Italy

Institute on Membrane Technology, National Research Council of Italy, ITM–CNR, Rende, Italy

Phosphate (also referred as phosphorus in some literatures which in fact is one of its constituting

elements) is a vital constituent for plants, animals, and human. Under natural circumstances, the presence of phosphorus is rare in water. Human activities have, however, changed the natural picture. Phosphorus enters into freshwater through several sources originating from domestic, industrial, and agricultural wastes. Phosphorus is commonly present into aqueous solutions in forms of orthophosphate, polyphosphate, and organic phosphorus compounds. The type of phosphorus associated with each source is generally different. Leaching from naturally occurring mineral resources, food processing effluents, and lands enriched with fertilizers play a significant role in contaminating the water with phosphorus that gives rise to eutrophication defined as the excess of nutrients into a stream that deteriorates the quality of water by stimulating the excessive growth of plants. Eutrophication causes excessive growth of blue-green algae causing pollution problems. The situation becomes further complex when bacteria ingest dead algae leading to the elimination/deficiency of dissolved oxygen into the water and rise in concentration of nutrients and related organic compounds. The depletion of dissolved oxygen can affect the marine life destructively. On the other hand, toxic nature of the compounds produced by blue-green algae has been reported in some studies. The algal bloom has been indicated a big problem for portable water treatment plants. On the other hand, the primary source of phosphate is apatite, and its extraction process is highly energy intensive and causes environmental problems. Therefore, the development of a closed loop cycle for phosphorus by its removal and recycling has gained significant attention recently.

It is worth to note that only orthophosphate can be precipitated and separated from aqueous solution. Both biological and chemical treatments have been applied to lower down the phosphorus concentration into the effluent to its desired level. In chemical treatment, coagulant comprising of multivalent metal ions is mixed with the wastewater containing phosphate, and precipitates of inorganic phosphate are separated from the solution. Biological treatment comprises of anaerobic tanks placed upstream of an aeration tank. The

main objective is the selective enrichment of polyphosphate-accumulating organisms in the sludge. These bacteria possess the capability to accumulate a huge quantity of polyphosphate. The biomass can be separated from treated water at the end of the process. The conventional biological processes generally do not meet the required criteria. On the other hand, chemical treatment suffers the drawbacks of high chemical cost and large volume of sludge produced. Therefore, a combination of biological and chemical treatment is also applied to achieve desired level of 1–2 ppm established by most of the countries. Several new technologies to remove phosphate from wastewater have emerged. The main examples include calcium-sequestered phosphate removal, magnetic separation, and adsorption.

Recently, some attentiveness has been observed in application of membrane operations to treat wastewater containing phosphate, mainly due to their capability to achieve an effluent of very high quality (as low as 0.008 ppm of phosphorus). Both suspended and dissolved forms can be removed by using membrane techniques. Reverse osmosis and nanofiltration have been applied to treat the effluents containing phosphorus. Thanks to the capability of the processes to remove multivalent and monovalent ions, very high phosphorus removal efficiency can be achieved (Lee et al. 2014). On the other hand, the retentate contains phosphorus in much concentrated form causing the disposal issues. The biological and chemical treatments traditionally apply gravity clarifiers and filtration separation which are insufficient to separate all chemical and biological entities present and cannot capture all the phosphate. Traditional operations have been integrated with membrane-based separation to achieve small footprint and decoupling of hydraulic retention time from solid retention time and to improve the effluent quality. Membrane bioreactors, tertiary membrane operations, and RO have been applied in large-scale installations, and attractive results have been achieved. Innovative membrane operations including forward osmosis, membrane distillation, and electrodialysis are being investigated for phosphorus removal from various waste streams. Some

studies also report a high process cost related with membrane operations (Jiang et al. 2004). The interest in membrane-based operations lies not only in purifying the water but also in recovering the phosphorus and reintroducing it into the cycle.

Photocatalysis with Membrane Distillation

Leonardo Palmisano

Dipartimento di Energia, Ingegneria dell'Informazione e Modelli Matematici (DEIM), Università di Palermo, Palermo, Italy

Photocatalysis by polycrystalline semiconductor oxides is being successfully applied to the abatement of organic and inorganic pollutants both in gas and in liquid phases. In order to increase the efficiency of this method, the coupling of this technology with the membrane separation process has been the object of investigation. In this combination, the membrane may act in different ways: to confine the photocatalytic powder in the reacting suspension, to selectively separate the photoreaction products, or to be the support of photocatalyst. Recent studies in which different types of membranes (such as distillation, dialysis, nanofiltration, pervaporation, and osmosis membranes) were used in hybrid systems have been reviewed by Loddo et al. (2009) describing perspectives and future possible application of the synergy between membranes and photocatalytic reactors. An additional advantage of coupling is

that the photocatalyst prevents the microbial fouling offering a strong potential for the use of new types of thin-film-composite membrane.

In the following, some studies concerning in details the application of photocatalysis and membrane distillation are reported.

To solve problems concerning separation of photocatalyst as well as products and byproducts of photodecomposition from the reaction mixture, the application of photocatalytic membrane reactors (PMRs) is a promising method. The PMRs described in literature combine photocatalysis with pressure-driven membrane techniques, such as nanofiltration (NF), ultrafiltration (UF), and microfiltration (MF). A serious problem with application of these membrane techniques can be membrane fouling, which is especially observable with MF and UF. The results of the investigation on the possibility of coupling photocatalysis and membrane distillation (MD) for degradation of organic pollutants in aqueous solution were described by Mozia et al. (2005). Acid Red 18 was applied as model dye and titanium dioxide Aeroxide (R) P25 (Degussa, Germany) was used as photocatalyst. In the first step of the research, the effect of the presence of TiO_2 in a feed on the permeate flux was investigated. It was found that the addition of TiO_2 P25 did not affect the distillate flux, regardless of the catalyst concentration applied. In order to select the best process conditions in terms of photocatalyst concentration and temperature of feed solution batch tests were performed. On the basis of these experiments, TiO_2 concentration and feed temperature in the reactor were set at 0.3 g/dm^3 and 333 K, respectively. The hybrid process photocatalysis -MD was conducted in a simultaneous mode. After 5 L of permeate the model dye was removed completely, whereas total organic carbon (TOC) concentration was lowered down to 20 % of the initial value.

Mozia et al. (2007) investigated on the possibility of coupling photocatalysis and direct contact membrane distillation (DCMD, MD) for degradation of azo dyes (Acid Red 18, Acid Yellow 36, and Direct Green 99) in aqueous solution. TiO_2 Aeroxide (R) P25 (Degussa, Germany) was used as the photocatalyst. It was found that the

addition of TiO₂ P25 to the feed did not affect the distillate flux, regardless of the catalyst concentration applied. The MD process was very effective in separation of photocatalyst particles. After 5 h of the experiment, the turbidity of distillate was similar to that measured for ultrapure water, regardless of the TiO₂ loading used. The highest effectiveness of photodecomposition was obtained in case of Acid Red 18, whereas Acid Yellow 36, which has the lowest molecular weight among the dyes used, was degraded with high difficulty. The composition of the feed solution slightly influenced the quality of distillate. Among the volatile compounds that passed through the membrane, some organic compounds were present as indicated by the measurements of TOC concentration.

An anatase-phase TiO₂ was applied for degradation of Acid Yellow 36 (AY36) in the PMR coupling photocatalysis and direct contact membrane distillation (DCMD) by Mozia et al. (2009). The effect of different process parameters such as dye concentration, reaction temperature, and photocatalyst loading on the effectiveness of degradation of AY36 was investigated. Moreover, in order to compare the effectiveness of AY36 photodegradation during photocatalysis alone and the hybrid process, additional experiments without application of the membrane distillation (MD) were conducted. The addition of TiO₂ to a feed did not affect the permeate flux, regardless of the process conditions applied. The latter remained constant during about 400 h of experiments. The highest decolorization of AY36 solution during hybrid process was observed at the highest photocatalyst loading applied (0.5 g TiO₂/dm³). The increase of the reaction temperature from 313 to 333 K resulted in an increase of the photodegradation rate of AY36. After 5 h of the hybrid process, the effectiveness of dye degradation calculated on a basis of AY36 mass in a feed solution amounted to 31 %, 36 %, and 42 % at reaction temperatures 313–333 K. Similar results were obtained when photocatalysis was conducted in the MD installation but with the MD module disconnected. An improvement of AY36 photodegradation was achieved by decreasing the initial dye

concentration. The best configuration seemed to be the PMR one by taking into account the rate of azo dye degradation and the quality of the product.

The investigations on the photodegradation of a nonsteroidal anti-inflammatory drug ibuprofen sodium salt (IBU) in a photocatalytic membrane reactor (PMR) coupling photocatalysis using suspended TiO₂ and direct contact membrane distillation was also described by Mozia et al. (2012). The influence of solution composition in terms of (i) pH (pH 3, pH 6.5, and pH 10), (ii) presence of inorganic salts (NaCl, Na₂SO₄, NaHCO₃, NaNO₃, and Na₃PO₄), and (iii) turbidity (bentonite, 13.5–103 NTU) on the effectiveness of IBU removal was especially investigated. The highest effectiveness of IBU photodegradation was obtained at pH 6.5. No influence of the presence of NaCl, NaNO₃, and Na₂SO₄ on the effectiveness of degradation and mineralization of IBU was found. NaHCO₃ and Na₃PO₄ did not affect the effectiveness of degradation of IBU; however, the efficiency of mineralization decreased significantly. The increased turbidity of feed solution did not affect IBU removal in the PMR.

Photocatalyst

Leonardo Palmisano

Dipartimento di Energia, Ingegneria
dell'Informazione e Modelli Matematici (DEIM),
Università di Palermo, Palermo, Italy

Photocatalyst can be defined as a substance that is able to produce, by absorption of ultraviolet, infrared, or visible light, chemical transformations of reaction partners, repeatedly coming with them into various chemical interactions without the occurrence of a permanent modification of its chemical composition. After each cycle of interaction between the reagent(s) and the photocatalyst, the chemical composition of the last is regenerated. The presence of a photocatalyst gives rise to an enhancement of the rate of a chemical reaction or its initiation under ultraviolet, infrared, or visible light illumination, and the role of light is to photo-excite the solid that works as the photocatalyst (Braslavsky et al. 2011). Notably, in some cases, light can be absorbed by the adsorbed reacting species that can be transformed and the solid photocatalyst works only as an adsorbent.

The materials that are generally used as photocatalysts are semiconductor solids with a band gap energy that is defined as the energy difference between the nonconductive and the conductive state of the material. The band gap energy can be also defined as the energy difference between the top of the valence band and the bottom of the conduction band. The photo-excitation of the solid occurs when light of suitable energy (higher than the value of the bandgap energy) induces the separation of electron and hole pairs by migration of electrons from the valence to the conduction band:

Photocatalyst

The photo-produced electrons and holes can give rise to reduction and oxidation reactions,

respectively, with adsorbed reacting species (Voïnov and Augustynski 1997).

The semiconductor photocatalyst is more frequently used both as powders (micro- or nanocrystalline samples) and films is bare polycrystalline TiO_2 in the anatase phase (Augugliaro et al. 2010) but also the other polymorphic rutile and brookite phases have been used. Moreover, the formation of nanorods, nanotubes, and nanowires under particular experimental conditions has been reported (Augugliaro et al. 2010). TiO_2 can be also doped with various transitional or rare earth metal species and non-metal species of N, C, S, and F. Sensitization with (metal) phthalocyanines and porphyrins to extend the light absorption in the visible region and/or to increase the lifetime of the photo-produced electron-hole pairs has been also proposed (Wang et al. 2010). Metallization with Pt or other noble metals has proved to be beneficial to induce some photo-reduction reactions, as for instance H_2 production from H_2O (Chiarello et al. 2011). Other oxides as for instance ZnO , WO_3 , MoO_3 , Fe_2O_3 , ZrO_2 , sulfides as ZnS , CdS , MoS_2 , or polyoxometalates as the heteropolyacid $\text{H}_3\text{PW}_{12}\text{O}_{40}$ have been also successfully tested as photocatalysts (Di Paola et al. 2012). They have been also mixed with or supported on SiO_2 or Al_2O_3 with the aim to increase the surface area and to have the possibility to improve adsorption of the reacting species before their chemical transformation on photoactive sites of adjacent particles of the semiconductor photocatalyst. They have been also used in combination with membranes forming devices called “photocatalytic membrane reactors” (Molinari et al. 2010).

Some photocatalysts are not (photo)stable in liquid-solid systems, especially in aqueous environments and the extent of this instability strongly depends on the pH conditions. For instance, (i) anodic photocorrosion is observed for ZnO and various sulfides and (ii) the recovery of polyoxometalates from the reacting medium is problematic, due to their high solubility. The above phenomena generally are not observed when the photoreactions are carried out in gas-solid systems, although in the latter system deactivation of photocatalyst has been sometimes

observed, depending on the type of reagent molecules and on the experimental conditions used, as for instance the presence of water vapor.

- chemical interactions without the occurrence of a permanent modification of its chemical composition. After each cycle of interaction between the reagent(s) and the photocatalyst, the chemical composition of the last is regenerated. The presence of a photocatalyst gives rise to an enhancement of the rate of a chemical reaction or its initiation under ultraviolet, infrared, or visible light illumination and the role of light is to photoexcite the solid that works as the photocatalyst (Braslavsky et al. 2011). The membrane has the task to immobilize the photocatalyst and to act as a molecular separation barrier for the reagents and/or reaction products (Molinari et al. 2002). A thin layer of a photocatalyst can be considered in principle a photocatalytic membrane, although the performance of some of them has not been reported.
- Some photocatalytic polysulfone membranes with the photocatalyst deposited and entrapped in the membrane were prepared and characterized by Molinari et al. (2002). It was found that adsorption of the pollutant on the membrane and membrane rejection play an important role in the global membrane performance showing interesting perspectives and synergy for coupling photocatalysis and membranes.
- Albu et al. (2007) showed a simple and robust fabrication process of a dense and free-standing membrane consisting of vertically oriented, both-side-open TiO₂ nanotubes. This membrane structure allows direct, size-selective, flow-through photocatalytic reactions with a very high efficiency.
- A semitransparent TiO₂ film with extraordinarily high photocatalytic activity was prepared by Sopyan et al. (1996) on a glass substrate by sintering a TiO₂ sol at 450 °C. Crystallographic analysis by X-ray diffraction and Raman spectroscopy showed that the film was purely anatase. The photocatalytic properties of the film were investigated by measuring the photodegradative oxidation of gaseous acetaldehyde at various concentrations under strong and weak UV light irradiation conditions. The photocatalytic activity of the film was higher than that of one of the most active commercial TiO₂ powders, Degussa P-25. The kinetics of acetaldehyde degradation as

Photocatalytic Membrane

Leonardo Palmisano

Dipartimento di Energia, Ingegneria dell'Informazione e Modelli Matematici (DEIM), Università di Palermo, Palermo, Italy

A photocatalytic membrane can be defined as a combination between a photocatalyst and a membrane. The photocatalyst is able to produce, by absorption of ultraviolet, infrared, or visible light, chemical transformations of reaction partners, repeatedly coming with them into various

catalyzed by the TiO₂ film as well as by P-25 powder were analyzed in terms of the Langmuir-Hinshelwood model.

TiO₂ and Ag-TiO₂ catalysts were supported in the form of thin layers by a dip-coating procedure on quartz substrate by Herrmann et al. (1997). The resulting materials were characterized by SEM/EDX, XRD, XPS, and UV-Vis absorption spectroscopy. The immobilized catalysts were tested in the photocatalytic degradation of malic acid and the increase of the photocatalytic activity can be explained by the enhanced electron-hole pair separation efficiency due to trapping of electrons by metallic Ag.

A novel chemistry method for the fabrication of robust nanostructured TiO₂ photocatalysts was developed by Choi et al. (2006). Such materials can be applied for developing efficient photocatalytic systems to be used for water treatment. The mesoporous photocatalytic TiO₂ membranes were synthesized via a simple method that involves dip-coating of appropriate substrates into an organic/inorganic sol composed of isopropanol, acetic acid, titanium tetraisopropoxide, and polyoxyethylene sorbitan monooleate surfactant (Tween 80) followed by calcination of the coating at 500 °C. Controlled hydrolysis and condensation reactions were achieved through in-taking of water molecules released from the esterification reaction of acetic acid with isopropanol. The subsequent stable incorporation of Ti-O-Ti network onto self-assembled surfactants resulted in TiO₂ photocatalysts with enhanced structural and catalytic properties. The properties included high surface area (147 m²/g) and porosity (46 %), narrow pore size distribution ranging from 2 to 8 nm, homogeneity without cracks and pinholes, active anatase crystal phase, and small crystallite size (9 nm). These TiO₂ photocatalysts were highly efficient for the destruction of methylene blue and creatinine in water. High water permeability and sharp polyethylene glycol retention of the prepared photocatalytic TiO₂/Al₂O₃ composite membranes evidenced the good structural properties of TiO₂ films. In addition, the multi-coating procedure enabled to control the physical properties of TiO₂ layer such as the coating thickness,

amount of TiO₂, photocatalytic activity, water permeability, and organic retention.

TiO₂ dispersed in polyester acrylate membranes was tested as a photocatalyst in the phenol mineralization reaction in the presence of O₂ by D'Arienzo et al. (2010). A kinetic study indicated that the embedded oxide maintains significant catalytic activity, and the result was first attributed to the homogeneous dispersion inside the polymeric host of TiO₂ nanocrystals. Furthermore, an investigation of the photogenerated charge carriers in the photocatalyst indicated that electrons are trapped on Ti³⁺ centers, while holes are trapped on C-centered species of the polymer matrix. In the presence of O₂, the C-centered radicals of the polymer transform into peroxy radicals, improving the charge separation in the polymer-embedded oxide with respect to the powder. The positive interference of the polymer matrix is responsible for the enhanced photoactivity of the embedded TiO₂.

Kim et al. (2003) proposed a hybrid thin-film-composite (TFC) membrane consisting of self-assembly of TiO₂ nanoparticles with photocatalytic destructive capability on microorganisms as a novel mean to reduce membrane biofouling. Microbial biofouling does not allow to realize high permeability over a prolonged period of reverse osmosis operation. The antifouling and fouling mitigation on the actual commercialized TFC was verified. TiO₂ anatase nanoparticles (≤10 nm) were prepared from the controlled hydrolysis of titanium tetraisopropoxide and characterized by X-ray diffraction (XRD) analysis and transmission electron microscopy (TEM). TFC membrane was prepared by self-assembly of the TiO₂ nanoparticles through coordination and H-bonding interaction with the COOH functional group of aromatic polyamide thin-film layer. The hybrid membrane was shown to possess photobactericidal effect on *Escherichia coli* (*E. coli*) under UV light illumination. Introduction of TiO₂ nanoparticles on the actual commercial TFC membrane and application of reverse osmosis field test after exposure to microbial cells indicated the occurrence of a substantial prevention against the microbial fouling showing a less loss of reverse osmosis permeability.

Photocatalytic Membrane Reactor

Leonardo Palmisano

Dipartimento di Energia, Ingegneria
dell'Informazione e Modelli Matematici (DEIM),
Università di Palermo, Palermo, Italy

A photocatalytic membrane reactor can be defined as a device existing in various configurations which combine a photocatalyst and a membrane to produce chemical transformations.

Some experimental results obtained by using various configurations of photocatalytic

membrane reactors (PMRs) have been discussed by Molinari et al. (2002). The configurations studied were (i) irradiation of the cell containing the membrane, with three sub-cases: (i(1)) catalyst deposited on the membrane; (i(2)) catalyst in suspension, confined by means of the membrane; (i(3)) entrapment of the photocatalyst in a PSF membrane; and (ii) irradiation of the recirculation tank and catalyst in suspension confined by means of the membrane. In the case of “(i),” a preliminary investigation of membrane stability under UV irradiation was carried out. PMR characterization in photodegradation tests was mainly carried out in a recycle batch membrane reactor and, in some cases, in a continuous membrane reactor. The comparison between the first set of results, where the membrane was used only as a support for the photocatalyst, and the newest ones, where the adsorption of the pollutant on the membrane and membrane rejection play an important role in the global reactor performance, showed interesting perspectives and synergy for coupling photocatalysis and membranes. Furthermore, the configuration where the recirculation tank was irradiated and the catalyst was used in suspension appeared to be the most interesting for industrial applications. For example, in reactor optimization, high irradiation efficiency, high membrane permeate flow rate, and selectivity can be obtained by sizing separately the “photocatalytic system” and the “membrane system” and taking advantage of all the best research results for each system.

A photocatalytic membrane reactor was tested for degradation of toxic organic species dissolved in water (Molinari et al. 2000). The catalyst, TiO_2 P25 Degussa, was immobilized by means of a flat sheet polymeric membrane and 4-nitrophenol (4-NP) was used as a model molecule to evaluate the reactor performance. A preliminary investigation of the stability, under UV irradiation, of some eligible polymeric membranes was carried out by using scanning electron microscopy (SEM), optical microscopy (OM), determinations of water permeation flux (WPF), and total organic carbon (TOC). These tests showed that commercial membranes made of fluoride + PP (FS 50 PP-Dow), polysulfone + PP (GR 51 PP-TechSep), and polyacrylonitrile (PAN-TechSep) seemed to be quite

stable to UV light over a 24 h period of irradiation. Immobilization of TiO_2 onto membranes by ultrafiltrating TiO_2 suspensions showed an optimal layer density slightly >2.04 mg TiO_2 per square cm of membrane surface area. Results obtained from membrane reactor studies indicated that the observed initial rate constants for the degradation of 4-NP were almost independent on the amount of TiO_2 employed over the range $0.76\text{--}4.08$ mg/cm². A 50 % weight degradation of 4-NP after 5 h of irradiation in the presence of air was obtained. Instead, an almost complete degradation of 4-NP was observed in the presence of TiO_2 suspended in the solution and pure oxygen. The permeate deriving from the membrane photoreactor was clear, and 4-NP concentration was approximately equal to that found in the retentate. The possibility of the continuous reuse of the photocatalyst and the continuous separation of products from the reaction medium gives some advantages over traditional approaches.

The ability of cross-flow ultrafiltration (UF) combined with photocatalytic reactions to separate TiO_2 photocatalysts from treated water in photocatalytic drinking water treatment was studied by Lee et al. (2001). The effect of natural organic matter (i.e., humic acids) and cross-flow velocities on UF fluxes and organic removal was explored with and without UV irradiation in the photocatalytic reactor. The interaction between the two solutes in the system, humic acids and TiO_2 photocatalysts, played a significant role in the formation of dense cake layers at the membrane surface, leading to a greater flux decline during ultrafiltration of TiO_2 particles. According to visual observations of the used membranes and the estimation of back-transport velocities of the solutes, a substantial amount of TiO_2 deposited on the membrane induces more humic acids to accumulate at the membrane through the adsorption of humic acids onto TiO_2 particles. The humic acid-laden TiO_2 particles offered more than four times higher specific cake resistance with a substantially increased compressibility coefficient than TiO_2 particles alone. The higher the cross-flow velocities, the greater the UV254 removal achieved. This was because the rise of cross-flow velocities contributed to the reduction of concentration

polarization at the membrane surface, thereby resulting in a decrease of the driving force for humic acids to pass through the membrane. When photocatalytic reactions took place with UV illumination, UV254 removal efficiencies of the permeate were improved markedly, and also the permeate flux was kept at a constant level without any sign of fouling. Although humic acids were not completely mineralized by photocatalysis, the degradation of the humic acids helped to enhance the UF flux, as they were transformed into less absorbable compounds.

The photodegradation of different pharmaceuticals [furosemide, ranitidine (hydrochloride), ofloxacin, phenazone, naproxen, carbamazepine, and clofibric acid] in aqueous medium at various pHs by using a batch photoreactor and a photocatalytic membrane reactor working in recirculation regime was carried out by Molinari et al. (2006). Polycrystalline TiO_2 was used as the photocatalyst, and different membranes (NTR 7410, PAN GKSS HV3/T, N 30 F, NF PES 10) were tested. A different adsorption of the substrates onto the catalyst surface was observed owing to the hydrophilic/hydrophobic character of the catalyst, depending on the pH. The photodegradation of the seven molecules in the batch reactor was successfully carried out, and the behavior was in accordance with pseudo-first-order kinetics. Furosemide and ranitidine were selected to carry out the study of rejection and photodegradation in the hybrid membrane system. The permeate flux of the treated water was in the $31.5\text{--}60.0$ L/(h m²) range for NTR 7410 membrane, whereas rejection values in the range 10–60 % for furosemide and 5–30 % for ranitidine in the dark (without photoreaction) were found. The degradation in the hybrid membrane photoreactor showed that the photocatalyst was retained by the membrane in the reaction ambient, while the membrane rejection toward the pollutants was not very satisfactory. A net decrease of the rejection down to 0 was observed in the contemporary presence of light, photocatalyst, and oxygen.

A batch-recirculated photoreactor was combined with a hollow fiber membrane ultrafiltration (UF) unit for heterogeneous photocatalysis applications (Sopajaree et al. 1999). The operation and

modeling of the UF process component and the performance of the integrated photoreactor-UF process assembly were studied. Methylene blue and titanium dioxide (Degussa P-25) were used as the test pollutant and photocatalyst, respectively. The influence of cross-flow velocity, transmembrane pressure, and TiO_2 dose on the permeate flux through the hollow fiber membrane was described. These data are modeled on the basis of concentration polarization and gel layer formation at the membrane surface/feed slurry boundary. The operation of the integrated photoreactor-UF assembly over ten repeated cycles was experimented. Photocatalyst separation was complete as gauged by nephelometric turbidity measurements. However, a systematic degradation in the photocatalyst performance was noted with each repeated cycle. Dynamic laser light-scattering data were consistent with agglomeration of the TiO_2 particles as a result of the UF process and suggest a possible factor in the degraded photocatalytic activity.

A photocatalytic reactor membrane pilot system, employing UV/ TiO_2 photocatalysis, was evaluated by Benotti et al. (2009) for its ability to remove 32 pharmaceuticals, endocrine-disrupting compounds, and estrogenic activity from water. Twenty-nine of the targeted compounds in addition to total estrogenic activity were greater than 70 % removed, while only three compounds were less than 50 % removed following the highest level of treatment (4.24 kWh/m^3). No estrogenically active transformation products were formed during treatment. Additionally, the unit was operated in photolytic mode (UV only) and photolytic plus H_2O_2 mode (UV/ H_2O_2) to determine the relative amount of energy required. Based on the electrical energy per order (EEO), the unit achieved the greatest efficiency when operated in photolytic plus H_2O_2 mode for the conditions tested.

Photocatalytic Membrane Reactor: Conversion of Organic Compounds

Raffaele Molinari

Dipartimento di Ingegneria per l'Ambiente e il Territorio e Ingegneria Chimica (DIATIC),
Università della Calabria, Rende, Italy

Photocatalytic synthesis in membrane reactors is still at a preliminary research stage, despite the great potentiality of photocatalytic processes, especially when they are coupled with a membrane separation system.

The possibility of using a membrane photoreactor for organic synthesis, developing a hybrid system in which the photocatalytic reaction and the separation of the desired product occurs in one step is of high interest.

Some results obtained in a photocatalytic membrane contactor (PMC) for the one-step synthesis of phenol, and its simultaneous separation, are reported by Molinari et al. (2009). TiO_2 has been used as catalyst, benzene as both reactant and extraction solvent, and a polypropylene

membrane to separate the organic phase from the aqueous reactive environment. To avoid secondary products and to obtain an efficient phenol production, the use of a membrane system, with high phenol permeability and complete rejection of the catalyst, coupled with the photocatalytic process, seems a useful solution. The membrane photoreactor built in this study consists of an external lamp placed on a batch reactor containing the aqueous solution with the catalyst in suspension; by means of a peristaltic pump, the solution is withdrawn from the photocatalytic reactor to a membrane contactor module in which a benzene solution is present as strip phase.

A set of preliminary experiments were performed in order to select the operating conditions to be employed in the batch and membrane systems. Due to the low solubility of benzene in water and to its high volatility, it was necessary to work with an excess of substrate in solution. By comparing the data in batch experiments obtained at pH values equal to 5.5 and 3.1, it was observed that the more acidic pH condition allowed to obtain a slightly increase of phenol production in the aqueous phase and a constant flux in the organic phase after 2 h (1.27 mmol/hm^2). Moreover, the area of the three main HPLC peaks detected at retention times of 3.0, 3.6, and 3.9 min indicated that a lower formation and extraction of these intermediates occurred at the acidic pH.

Other works concerning photocatalytic conversions are reported in the following. Selective oxidation of various primary and secondary alcohols was studied by Pillai and Sahle-Demessie (2002) in a gas phase photochemical reactor using immobilized TiO_2 catalyst. An annular photoreactor was used at 463 K with an average contact time of 32 s. The system was found to be specifically suited for the selective oxidation of primary and secondary aliphatic alcohols to their corresponding carbonyl compounds. Benzylic alcohols gave higher conversions, however, with more secondary reaction products. The reaction mechanism for various products formed was explained. The effects of different reaction parameters, such as O_2 /alcohol ratio, water vapor, UV light, and contact time, were studied. The

presence of oxygen was found to be critical for the photooxidation. Water vapor in the feed was also found to be beneficial, although it was not as critical as in hydrocarbon oxidation, where it was necessary for hydroxylating the catalyst surface and sustaining its activity. In alcohol oxidation, surface hydroxylation could be partially provided by the hydroxyl groups of the alcohol itself. Catalyst deactivation was also observed and it was attributed to the surface accumulation of reaction products. However, the catalyst regained its original activity after regeneration by calcination in air for 3 h at 723 K.

Selective photocatalytic oxygenation of various substrates was achieved using organic photocatalysts via photoinduced electron transfer reactions of photocatalysts with substrates and dioxygen under visible light irradiation (Fukuzumi and Ohkubo 2013). Photoinduced electron transfer from benzene to the singlet excited state of the 3-cyano-1-methylquinolinium ion enabled the oxidation of benzene by dioxygen with water to yield phenol selectively. Alkoxybenzenes were obtained when water was replaced by alcohols under otherwise the same experimental conditions. Photocatalytic selective oxygenation reactions of aromatic compounds was also achieved using an electron donor-acceptor, 9-mesityl-10-methylacridinium ion acting as a photocatalyst, and dioxygen as an oxidant under visible light irradiation.

The most recent advances in the application of heterogeneous photocatalysis to synthesize valuable compounds by selective oxidation and reduction are reported by Palmisano et al. (2010).

The photocatalytic oxidation of 4-methoxybenzyl alcohol in water was performed in a fixed bed continuous annular reactor by using a home-prepared TiO_2 catalyst supported on Pyrex glass beads (Yurdakal et al. 2010). The investigation was aimed to modeling the complex kinetics of the photoprocess which occurs through two parallel pathways: (i) partial oxidation to the corresponding aldehyde and (ii) total oxidation to CO_2 and H_2O . On these grounds, the influence of liquid flow rate, inlet concentrations of alcohol and oxygen, catalyst amount, and irradiation power on the photoreactivity were studied.

A kinetic model like that of Langmuir-Hinshelwood satisfactorily fitted the experimental results and allowed determination of the values of model parameters. It was found that all these parameters are positively affected by an increase of radiant energy absorbed by the catalyst. All the reactivity results indicate that the partial oxidation pathway is favored by the low flux of absorbed photons and by low oxygen coverage on the TiO₂ surface; opposite conditions favor the mineralization pathway.

The photoproduction of vanillin was studied in aqueous medium starting from *trans*-ferulic acid, isoeugenol, eugenol, or vanillyl alcohol by using both commercial and home-prepared TiO₂ samples as photocatalysts (Augugliaro et al. 2012). The visible light-induced oxidation of *trans*-ferulic acid by TiO₂ photocatalysis was also carried out under visible light via the formation of a charge-transfer complex (Parrino et al. 2012). A drawback for this type of photoreaction is the relatively low selectivity observed and the presence of other products. The combination of photocatalysis and pervaporation by using nonporous membranes has been suggested to separate the vanillin or other aldehydes from the irradiated suspension to avoid their subsequent oxidation, increasing in such a way the selectivity (Camera Roda et al. 2010; Camera Roda et al. 2013). The mild experimental conditions used suggest that heterogeneous photocatalysis could be in some cases an alternative green route for replacing environmentally hazardous processes with safe and energy efficient routes.

Photocatalytic Membrane Reactor: Degradation of Organic Compounds

Raffaele Molinari

Dipartimento di Ingegneria per l'Ambiente e il Territorio e Ingegneria Chimica (DIATIC),
Università della Calabria, Rende, Italy

Degradation of organic compounds in photocatalytic membrane reactors has been one of the first applications in the combination of photocatalysis and membranes. The possibility of using a membrane photoreactor for degradation of organics, developing a hybrid system in which the photocatalytic reaction and the separation of the desired product occur in only one device, is of high interest. Some results obtained in this application are reported in the following.

The ability of cross-flow ultrafiltration (UF), combined with photocatalytic reactions, to separate TiO₂ photocatalysts from treated water in photocatalytic drinking water treatment was investigated by Lee et al. (2001). The effect of natural organic matter (i.e., humic acids) and

cross-flow velocities on UF fluxes and organic removal was explored with and without UV irradiation in the photocatalytic reactor. The interaction between the two solutes in the system, humic acids and TiO_2 photocatalysts, played a significant role in the formation of dense cake layers at the membrane surface, leading to a greater flux decline during ultrafiltration of TiO_2 particles. According to visual observations of the used membranes and the estimation of back-transport velocities of the solutes, a substantial amount of TiO_2 deposited on the membrane induced a higher amount of humic acids to accumulate at the membrane through the adsorption onto TiO_2 particles. The humic-acid-laden TiO_2 particles offered more than four times higher specific cake resistance with a substantially increased compressibility coefficient than TiO_2 particles alone. The higher the cross-flow velocities, the greater the UV254 removal achieved. This was because the rise of cross-flow velocities contributed to the reduction of concentration polarization at the membrane surface, thereby resulting in a decrease of the driving force for humic acids to pass through the membrane. When photocatalytic reactions took place with UV illumination, UV254 removal efficiencies of the permeate were improved markedly, and also the permeate flux was kept at a constant level without any sign of fouling. Although humic acids were not completely mineralized by photocatalysis, the degradation of the humic acids helped to enhance the UF flux, as they were transformed to less adsorbable compounds.

A photocatalytic reaction system, composed of solution and gas spaces divided by a thin Teflon film and TiO_2 -coated mesh or cloth, for the treatment of contaminated aqueous solutions was developed to be operated with enhanced aeration without bubbling of air in the solution (Villacres et al. 2003). First, the photocatalytic activities of TiO_2 particles immobilized on two kinds of support material, stainless steel mesh (SSM) and fiberglass cloth (FGC), were investigated for photocatalytic oxidation of 2-propanol, as a model volatile organic compound, dissolved in aerated aqueous solution. The TiO_2 particles immobilized on both support materials exhibited photocatalytic activity to oxidize 2-propanol into

acetone and carbon dioxide (CO_2), and the activity levels of the TiO_2 particles immobilized on the two kinds of support materials were comparable. Presumably due to the presence of a small amount of metal species originating in SSM that might work as reduction catalysts, molecular hydrogen H_2 was also liberated on the TiO_2 -immobilized SSM. Results of analysis of weight loss after photoirradiation suggested that the stability of the TiO_2 -immobilized FGC was better than that of the TiO_2 -immobilized SSM. On the basis of these results, FGC was employed in construction of a photocatalytic reactor equipped with an O_2 -permeable Teflon membrane in order to make oxygen pass from a gas space to a solution space and to keep the surface of the immobilized TiO_2 photocatalyst, facing an aqueous solution containing volatile organic compounds, saturated with dissolved O_2 . From the results of photocatalytic oxidative decomposition of 2-propanol, it was clarified that the surfaces of TiO_2 particles could be sufficiently supplied with O_2 from the gas space through the membrane to accelerate the oxidation.

Dyes are organic compounds used in textile, food, and drug industries, and their abatement represents one of the main problems in the treatment processes because generally they are very stable toxic compounds. Two commercial azo-dyes, i.e., Congo Red ($\text{C}_{32}\text{H}_{22}\text{N}_6\text{Na}_2\text{O}_6\text{S}_2$) and Patent Blue ($\text{C}_{27}\text{H}_{31}\text{N}_2\text{NaO}_6\text{S}_2$), in aqueous solution were degraded in a photocatalytic membrane reactor (Molinari et al. 2004) by using TiO_2 Degussa P25 as the catalyst. Different system configurations and irradiating sources were studied, and the influence of some operational parameters such as the pressure in the membrane cell and the initial concentration of the substrates were determined. A comparison between suspended and entrapped TiO_2 was also done. The experimental results showed a satisfactory degradation efficiency of the photocatalytic membrane process. The influence of various parameters (e.g., feed concentration, recirculation rate) has been discussed to obtain high reaction rates, operating stability, and high membrane rejection, both for substrates and by-products. Congo Red was photodegraded with higher rate under the same

experimental conditions probably due to its higher adsorption onto the catalyst surface. It was possible to treat successfully highly concentrated solutions (500 mg/L) of both dyes by means of a continuous process obtaining good values of permeate fluxes (30–70 L/m²h); this could be interesting for industrial applications. The reactor containing the suspended photocatalyst was significantly more efficient than the reactor containing the catalyst entrapped into the membrane.

An advanced oxidation process (AOP) with reactor capacity of 150 L, using ultraviolet (UV) radiation and TiO₂ photocatalyst, was evaluated for the destruction of toxic organic chemical, bisphenol A (BPA) by Thiruvengkatachari et al. (2005). TiO₂, in the form of powder, was suspended as slurry in the water avoiding the commonly adopted practice of immobilizing it onto a carrier material such as glass, concrete, or ceramics. Adsorption of BPA by TiO₂ was evaluated and was performed as a pretreatment to AOP. The combined effect of ozone with the AOP process was also studied. Coupling ozone with UV/TiO₂ brought about a synergistic effect on BPA degradation and 10 ppm of BPA, and the intermediate organic compounds were completely removed within 3 h. The highlight of this study was the simultaneous degradation of BPA and separation of TiO₂ particles from water after the photocatalytic treatment, in order to obtain reusable quality water. Separation of TiO₂ particles was carried out by a unique two-stage coagulation and settling process followed by submerged hollow fiber microfiltration membrane technique. With initial turbidity of 4,000 NTU, the turbidity of the final permeate water was well below 0.1 NTU. Some of the main advantages of this hybrid treatment system include the possibility of large-scale treatment, complete and efficient BPA and its organic intermediates degradation, easy separation and reuse of TiO₂ that resulted free from chemical coagulant contaminants, reusable quality water, and potentiality for continuous operation with simple process modifications.

A study of the photodegradation of different pharmaceuticals [furosemide, ranitidine (hydrochloride), ofloxacin, phenazone, naproxen,

carbamazepine, and clofibric acid] in aqueous medium at various pHs by using a batch photoreactor and a photocatalytic membrane reactor working in recirculation regime was carried out by Molinari et al. (2006). Polycrystalline TiO₂ was used as the photocatalyst, and different membranes (NTR 7410, PAN GKSS HV3/T, N 30F, NF PES 10) were tested. A different adsorption of the substrates onto the catalyst surface was observed owing to the hydrophilic/hydrophobic character of the catalyst, depending on the pH. The photodegradation of the seven molecules in the batch reactor was successfully carried out and the behavior was in accordance with pseudo-first-order kinetics. Furosemide and ranitidine were selected to carry out the study of rejection and photodegradation in the hybrid membrane system. The permeate flux of the treated water was in the 31.5–60.0 L/(h·m²) range for NTR 7410 membrane, whereas rejection values in the range 10–60 % for furosemide and 5–30 % for ranitidine in the dark (without photoreaction) were found. The degradation in the hybrid membrane photoreactor showed that the photocatalyst was retained by the membrane in the reaction ambient, while the membrane rejection toward the pollutants was not very satisfactory. A net decrease of the rejection down to 0 was observed in the contemporary presence of light, photocatalyst, and oxygen.

The combination of a dialysis membrane and a photocatalytic reactor into an original membrane photoreactor (MPR) to mineralize organic compounds contained in artificial turbid waters which were obtained by using natural clay named bentonite was studied by Azrague et al. (2007). Various systems have been described in the literature, combining photocatalysis with pressure-driven membrane techniques, such as nanofiltration (NF) and ultrafiltration (UF), but these systems can lead to membrane fouling. Only the combination of photocatalysis and membrane distillation avoids this problem, but it needs energy to reach pervaporation phenomena. The MPR system worked at ambient temperature, with the membrane used as a barrier for particles and to extract the organic compounds from the turbid water without transmembrane pressure. Thus it was

possible to separate the polluted turbid water from the photoreactor compartment and to separate TiO_2 continuously from the treated water. The photocatalytic reaction and dialysis were studied separately before the MPR process was developed. A model pollutant, 2,4-dihydroxybenzoic acid (2,4-DHBA), was mineralized from turbid waters by photocatalysis. By means of the membrane, the TiO_2 remained in the photoreactor compartment without filtration and bentonite was kept away from the photoreactor.

The degradation of toxic organic compounds such as trichloroethylene (TCE) in water, using a combined photocatalysis/microfiltration (MF) system, was focused by Choo et al. (2008). The performances of the hybrid system were investigated in terms of the removal efficiency of TCE and membrane permeability, in the presence or absence of humic acids and at different pHs. The fate of TCE during the photocatalytic reactions was checked in order to evaluate the feasibility of the photocatalytic membrane reactor (PMR). Greater TCE degradation (>60 %) was achieved with an increase in the TiO_2 dosage (up to 1.5 g/L) in PMR, but a substantially large TiO_2 dosage brought about a decrease in TCE degradation efficiency. The photocatalytic decomposition of TCE appeared to be more effective at acidic pH conditions than at a neutral or alkaline pH. The alkalinity and the addition of humic acids into the feedwater did not produce a significant effect on TCE degradation, while humic acids (whose dose was 1 mg/L as TOC) in the feedwater played a role in a decline of permeability by 60 %. Membrane permeability in the PMR was also affected by tangential velocities. An improvement of 60 % in flux was achieved when the tangential velocity increased from 0.19 to 1.45 m/s. This occurred because flow regimes can govern the deposition of TiO_2 particles on the membrane surface.

Photocatalytic Membrane Reactors for Refractory Pollutants Degradation

Marc Cretin^{1,2}, Julie Mendret¹ and Stephan Brosillon¹

¹Institut Européen des Membranes, ENSCM-UM-CNRS (UMR 5635), Université de Montpellier, Montpellier Cedex 5, France

²National School of Chemistry of Montpellier, University of Montpellier, Montpellier, France

The increasing emission of refractory organic pollutants has challenged the conventional water treatment. As one of the advanced treatment systems, photocatalytic oxidation has drawn significant attention in water treatment research because of its environmental compatibility and powerful oxidation ability. Photocatalysis is an acceleration of photoinduced reaction by the presence of a photocatalyst. Among the photocatalysts, titanium dioxide (TiO_2) has been proven to be an attractive and promising semiconductor catalyst in heterogeneous photocatalysis and in advanced oxidation

Photocatalytic Membrane Reactors for Refractory Pollutants Degradation,

Fig. 1 Main configurations of PMR, (a) photocatalyst in suspension and (b) photocatalyst coated on the membrane, inspired from Mozia (2010)

processes own to its unique photocatalytic efficiency. However, a main limitation remains: the separation of the catalyst from treated. Photocatalytic membrane reactor (PMR) with synthesized catalyst is thus a very promising method to overcome photocatalysis drawbacks (Mozia 2010). In such configuration, the membrane plays the role of a barrier for the photocatalyst and a selective barrier for the molecule to be degraded. The main advantage is to confine the photocatalyst in the reaction environment by means of the transmembrane flux, the control of the residence time of the molecule in the reactor, and the achievement of a continuous process with simultaneous catalyst and product separation from the reaction environment. It also allows some additional operations for catalyst recycling to be avoided, such as coagulation, flocculation, sedimentation, or filtration, and thus leads to energy saving and enables the size of the installation to be minimized. Finally, this configuration enables the main drawback of membrane processes to be overcome: the fact that it only transfers pollutant from a phase to another without treating it.

PMR can be divided into two main groups: photocatalyst in suspension or immobilized in/on

the membrane (Fig. 1). The major drawback of the first configuration (a) is the membrane fouling (leading to a decrease of the permeate flux) and the deterioration of the membrane surface when organic membranes are used. The second configuration (b) enables this drawback to be avoided as oxidation by hydroxyl radicals occurs on the external surface and within the pores of the membrane while reactants are permeating in a one pass flow. Main advantage of this configuration is to minimize mass transfer resistance between the bulk of the fluid and the semiconductor surface.

Concerning membrane with catalyst immobilized on the membrane surface, photoactive layer can be deposited using the dipcoating method followed by heat treatment: a membrane is dipped in a suspension of nanoparticles and then calcined (600 °C) to crystallize the TiO_2 (Mendret et al. 2013). For this, the use of ceramic membrane is less straightforward than polymeric membranes which can be more easily manipulated. In a PMR with TiO_2 immobilized, the membrane acts as a support for the catalyst and might act as a barrier for molecule present in the solution (initial compounds and products or by-products of their

Photocatalytic Membrane Reactors for Refractory Pollutants Degradation,

decomposition). The photodecomposition takes place on the membrane surface and thus membrane itself has to be irradiated. The main advantage is that membrane fouling could be reduced; thus permeate flux increased, because organic compounds which are responsible for fouling such as humic and fulvic acids are also decomposed as the surface of the membrane is reactive. Moreover, it was observed that deposition of titania on the membrane increases their hydrophilicity which contributes to fouling mitigation. Indeed, many studies have been conducted in the field of fouling mitigation of membranes (Gullinkala and Escobar 2010), and it is widely acknowledged that hydrophobic membrane surfaces have an obviously higher tendency to foul and to reduce permeability. Membrane surface properties such as hydrophilicity and charge determine the interaction between the membrane and the foulants. A hydrophilic membrane possesses a high surface tension and has the ability to form hydrogen bonds with water, and therefore a water layer exists between the membrane and the bulk solution which increases membrane hydrophilicity. As a consequence, such membranes are less prone to fouling. Moreover, it was experimentally put in evidence that TiO_2 layer under UV light enhances ceramic membrane wettability and enables higher and more stable flux to be reached rapidly (Fig. 2; Mendret et al. 2013).

Photocatalysis, in which solar photons are used to drive redox reactions to produce chemicals

on the surface of an irradiated semiconductor, is one of the main alternative solutions for renewable energy generation and environmental remediation.

In the category of photocatalytic materials, semiconductor materials have attracted considerable attention in the fields of solar energy conversion and environmental protection because it represents an easy way to utilize the energy of either natural sunlight or artificial indoor illumination. Of the many different photocatalysts, TiO_2 emerged in 1972 for the investigation of photonic energy conversion by photocatalytic method (Fujishima and Honda 1972). Since then, it has been the most widely studied and used in many applications because of its strong oxidizing abilities (Fujishima and Honda 1972; Nosaka et al. 2002, 2003a, b, 2004; Jańczyk et al. 2006; Fujishima et al. 2007) for the decomposition of organic pollutants, chemical stability, long durability, nontoxicity, low cost, and transparency to visible light.

Anatase- TiO_2 is well known as a semiconductor catalyst, which exhibits a better photocatalytic activity by irradiation of a light with energy greater than the band gap (3.2 eV) (Sopyan et al. 1994). The photocatalytic activity appears by irradiation of an ultraviolet (UV) light with wavelength shorter than 387 nm ($=3.2$ eV). The decomposition of harmful substances using the photocatalytic activity of anatase- TiO_2 has attracted a great deal of attention (Matsuda et al. 2000). This effect is attributed to the strong oxidant (hydroxyl radical), which generates at the surface of the TiO_2 crystals by the irradiation of UV light.

Doping of TiO_2 is one of the solutions to enhance/extend its photocatalytic properties. Utilizing Ag in conjunction with TiO_2 could potentially allow several different inactivation mechanisms to work in concert. Therefore, a synergism occurs between Ag and TiO_2 when Ag/ TiO_2 is used for inactivating microorganisms under UV radiation. Li et al. demonstrated, for example, that Ag-doping TiO_2 greatly enhanced the photocatalytic inactivation of viruses primarily by increasing $\text{HO}^\cdot$ production in addition to slightly increasing virus adsorption (Lig

et al. 2011). Wang et al. demonstrated that the deposition of Ag on the surface of TiO_2 would produce traps to capture the photoinduced electrons or holes, leading to the reduction of electron-hole recombination and thus improving the photocatalytic efficiency (Wang et al. 2008). The effect of Ag dopants on the lattice or surface of TiO_2 was also demonstrated to enable the catalyst to perform more effectively and shortens the illumination period (Lee and Hong 2005).

As demonstrated by Gleiter's group (Gleiter 1989), nanostructuring makes possible to design nanomaterials with enhanced properties or even generation of new functionalities which have not been obtained in conventional materials. This is the second solution to propose high-performance photocatalytic nanomaterials (Irie et al. 2009; Yashima et al. 2010; Liu et al. 2007). Small material size is generally beneficial for surface-dependent catalysis because it enhances specific surface area and also increased reactive sites. However, smaller material size is not always higher catalytic efficient because it can cause strong quantum confinement effect that increases the recombination probability of photogenerated electron-hole pairs (Chen et al. 2012; Song et al. 2013; Serpone et al. 2012). Therefore, photogenerated electron-hole pair migration requires a reduced recombination of suitable concentration gradient or potential gradient from the core to surface of materials that is correlated with morphology, structure, and surface properties of nanostructured materials.

Nowadays, because of their enhanced or even novel properties, photocatalytic nanomaterials have created more opportunities in extending the applications of photocatalytic materials in various fields such as water and air purifications, hydrogen generation, CO_2 reduction, dye-sensitized solar cells, antifogging surfaces, heat transfer and heat dissipation, anticorrosion, lithography, photochromism, solar chemicals production, and many others. They can be prepared using chemical routes such as sol-gel process and ammonia treatment of molecular precursors to exist in many compositions, in particular in oxide, oxynitride, and nitride systems.

Photocatalytic Process

Leonardo Palmisano

Dipartimento di Energia, Ingegneria dell'Informazione e Modelli Matematici (DEIM), Università di Palermo, Palermo, Italy

A photocatalytic process is a set of reduction and oxidation photocatalytic reactions occurring in the presence of a photocatalyst (see photocatalyst) that gives rise to one or more products starting from organic or inorganic substrate(s).

The distinction of the photocatalytic reactions in oxidation and reduction means that only the main product(s) derive(s) from oxidation or reduction,

respectively, of the main reagent(s). Noticeably, in fact, both the oxidative and reductive pathways are present in heterogeneous photocatalytic processes. Sometimes the reduction pathway produces species (e.g., $O_2^{\bullet-}$ by trapping electrons in the conduction band of a semiconductor photocatalyst) whose subsequent reaction (e.g., with H_2O) gives rise to $\bullet OH$ and $\bullet O_2H$ oxidant radicals.

The photoproducted holes can straightforwardly attack the adsorbed species or solvent molecules (for instance, H_2O) producing oxidant radical species. The following sketch represents the possible initial steps of a photocatalytic process (Fig. 1).

The heterogeneous photocatalytic oxidations are generally unselective, and several studies and applications have been reported, for instance, in the field of outdoor and indoor environment purifications to abate low concentrations of organic and inorganic pollutants (Serpone and Emeline 2005). The heterogeneous photocatalytic method appears to be efficient only in those cases where low concentrations of pollutants are present because the presence of high concentrations slows down the reaction rates. Moreover, it should be checked, with great care, both the absence of mass transfer phenomena controlling the reaction kinetics and the possible photocatalyst deactivation, due to possible accumulation of by-products and/or intermediates onto the photocatalyst surface which could block the (photo)active sites (particularly for long lasting runs in gas-solid systems). These problems are not dramatic in the aqueous systems. A moderate mixing of the reacting suspension is sufficient to guarantee the absence of a mass control on the reaction kinetics. The photocatalyst surface, in fact, is cleaned by production of a high number of oxidant radicals that induce consecutive attacks to the intermediates giving rise to their complete mineralization by means of several adsorption-desorption steps. In addition, the mineralization can proceed through intermediates that do not desorb into the bulk of solution, but are subjected to oxidant attacks onto the surface until the formation of CO_2 . Indirect evidence of this behavior in many cases is the detection of CO_2 soon after the starting of irradiation.

Heterogeneous photocatalytic processes have been more recently addressed also toward the

Photocatalytic Process,**Fig. 1** Photocatalytic Process

selective production of high-value molecules in mild experimental conditions by using suitable photocatalysts, solvent and starting substrates (Palmisano et al. 2010; Augugliaro and Palmisano 2010), and, in some cases, also membranes (Molinari et al. 2009).

Photocatalytic Processes by Membrane Operations

Raffaele Molinari

Dipartimento di Ingegneria per l'Ambiente e il Territorio e Ingegneria Chimica (DIATIC),
Università della Calabria, Rende, Italy

A photocatalytic process combined with membrane operations is a set of reduction and

oxidation photocatalytic reactions occurring in the presence of a photocatalyst (see “► Photocatalytic Process”) and a membrane giving rise to one or more products (see “► Photocatalytic Membrane Reactor”) starting from organic or inorganic substrate(s).

Photocatalysis and, in particular, heterogeneous photocatalysis is a process of great potentiality for pollutants abatement. To improve the overall performance of the photoprocess, heterogeneous photocatalysis has been often combined with physical or chemical operations, which affect the chemical kinetics and/or the overall efficiency. Various possibilities to couple heterogeneous photocatalysis with other technologies to photodegrade organic and inorganic pollutants dissolved in actual or synthetic aqueous effluents have been described by Augugliaro et al. (2006). These combinations increase the photoprocess efficiency by decreasing the reaction time with respect to the separated operations or they decrease the cost with respect to heterogeneous photocatalysis alone, generally in terms of light energy. Depending on the operation coupled with heterogeneous photocatalysis, two categories of combinations exist. When the coupling is with ultrasonic irradiation, photo-Fenton reaction, ozonation, or electrochemical treatment, the combination affects the photocatalytic mechanisms thus improving the efficiency of the photocatalytic process. When the coupling is with biological treatment, membrane reactor, membrane photoreactor, or physical adsorption, the combination does not affect the photocatalytic mechanisms, but it improves the efficiency of the overall process. The choice of the coupling is related to the type of wastewater to be

treated. A synergistic effect, giving rise to an improvement of the efficiency of the photocatalytic process, has been reported in the literature for many cases.

The influence of the type of nanofiltration membrane, initial concentration of pollutant, and pH on the photodegradation rate was investigated by Molinari et al. (2002) in discontinuous and continuous configurations in a photocatalytic membrane system with the lamp immersed in the suspension inside the photoreactor by using polycrystalline TiO_2 (Degussa P25) as the catalyst and humic acids, organic dyes, and 4-nitrophenol as the pollutants. Two membranes were tested, i.e., NF-PES-010 (Celgard, Germany) of polyethersulfone and NTR-7410 (Nitto Denko, Japan) of sulfonated polyethersulfone. The last one was chosen for all of the photoreactivity experiments because permeability and rejection tests indicated that it was able to hold both catalyst and small molecules carrying the same membrane charge (negative), thanks to the Donnan exclusion. Despite the fluxes ranged between 20 and 40 $\text{L h}^{-1} \text{m}^{-2}$ in operating conditions at 6 bar and these values were interesting for application purposes, the rejections of NTR-7410 nanofiltration membrane, obtained during operation of the membrane photoreactor in the degradation of humic acids, patent blue dye, and 4-nitrophenol, were significantly lower than those obtained in the absence of photodegradation, probably because of the small molecular size of the by-products and of the intermediate species produced during the photodegradation process. This means that in order to select a suitable membrane, rejection should be determined during operation of the photoreactor.

A batch-recirculated photoreactor was combined with a hollow-fiber membrane ultrafiltration (UF) unit for heterogeneous photocatalysis applications. The operation and modeling of the UF process on the performance of the integrated photoreactor-UF process was studied by Sopajaree et al. (1999). Methylene blue and titanium dioxide (Degussa P-25) were used as the test pollutant and photocatalyst, respectively. The influence of cross-flow velocity, transmembrane pressure, and TiO_2 dose on the permeate flux through the hollow-fiber membrane was described. The data were modeled

on the basis of concentration polarization and gel layer formation at the membrane surface/feed slurry boundary.

The photocatalytic degradation of natural organic matter (NOM) is an attractive option in the treatment of drinking water (Choo et al. 2008). The performance of a submerged photocatalytic membrane reactor (PMR) was investigated with regard to the removal of NOM and the control of membrane fouling.

The efficiency of a hybrid system combining photocatalysis and membrane filtration in a single module was investigated. Low-pressure submerged hollow-fiber membranes were used to retain the TiO_2 particles in the system by Chin et al. (2007) during the photodegradation of bisphenol A (BPA) as the model pollutant. Aeration was applied in the submerged membrane photoreactor (SMPR) to provide (i) mixing, (ii) dissolved oxygen, (iii) mechanical agitation (to prevent agglomeration of TiO_2 particles), and (iv) shear forces (to remove TiO_2 particles from the membrane surface). It was found that intermittent permeation enhanced the sustainability of the submerged membranes but showed no effect on the photoactivity of the system. An intermittence aeration frequency (IF) of 0.1 was sufficient to reduce the fouling rate of the membrane under the experimental conditions. The SMPR appears to be very effective and can achieve removal of low-concentration organics (such as BPA) in a compact, low-energy system. The combined photocatalytic and membrane processes have been more recently addressed also toward the selective production of high-value molecules in mild experimental conditions by using suitable photocatalysts, solvent, and starting substrates and membranes (Molinari et al. 2009a, b; Augugliaro and Palmisano 2010).

Photodegradation

Raffaele Molinari

Dipartimento di Ingegneria per l'Ambiente e il Territorio e Ingegneria Chimica (DIATIC),
Università della Calabria, Rende, Italy

Photodegradation concerns the breaking of a molecule to smaller molecules (degradation and/or mineralization) by means of the absorption of photons of suitable wavelength such as that found in the infrared radiation, visible light, and ultraviolet light of the solar spectrum. Photodegradation also includes the change of the shape of a molecule such as protein denaturation and the addition of other atoms or molecules. One type of photodegradation reaction is oxidation which is used to purify some drinking water and wastewater to destroy pollutants. Photodegradation can be photochemical and photocatalytic: in the first case only light is used, while in the second case a combination of light

and a semiconductor photocatalyst is used. In the photocatalytic oxidation process, organic pollutants are destroyed in the presence of semiconductor photocatalysts (e.g., TiO_2 and ZnO), an energetic light source, and an oxidizing agent such as oxygen or air. Photocatalytic degradation in aqueous medium is mainly dependent on the solution pH, catalysts and their composition, organic substrate type (usually pollutants) and concentration, light intensity, catalyst loading, ionic composition of wastewater, types of solvent, oxidant concentration, and calcination temperatures of the photocatalyst (Ahmed et al. 2010).

In the degradation of organic pollutants, various compounds such as dyes (Molinari et al. 2003), drugs (Molinari et al. 2006), pesticide and herbicide derivatives dominant in storm water, and wastewater effluent have been treated. In the photocatalytic process, the hydroxyl radical, which is generated from the oxidation of adsorbed water as $\text{OH}^\cdot$, is the primary oxidant species, while the presence of oxygen prevents an electron-hole pair recombination. In the photocatalytic degradation of pollutants, when the reduction process of oxygen and the oxidation of pollutants do not proceed simultaneously, there is an electron accumulation in the CB, thereby causing an increase in the rate of recombination of e^- and h^+ . Thus it is of paramount importance to prevent electron accumulation in efficient photocatalytic oxidation. In photocatalysis, TiO_2 has been studied extensively because of its high activity, desirable physical and chemical properties, low cost, and availability. Among the TiO_2 crystalline forms, anatase and rutile forms have been investigated extensively as photocatalysts. Anatase has been reported to be more active as a photocatalyst than rutile.

Heterogeneous photocatalysis involving zinc oxide (ZnO) emerges as a promising new route for water purification process in terms of the degradation and mineralization of dyes discharged into wastewater from textile and other industrial processes (Lam et al. 2012), although ZnO can give rise to anodic photocorrosion in aqueous systems, depending on the experimental conditions chosen.

Removal of nitrogen-containing organic compounds in wastewater by TiO_2 photocatalytic degradation is the result of a strong interaction among pollutant structures, TiO_2 properties, and photocatalytic reaction conditions. It is also clear that for each organic pollutant, a unique set of conditions may be needed for the optimal performance (Jing et al. 2011).

Solid-phase photocatalytic degradation for eco-friendly disposal of polymer such as waste plastics has been also studied. Composite plastics embedding photocatalysts into polymer matrix have excellent photocatalytic degradation activity. They could be degraded effectively in ambient air under sunlight exposure (Yang et al. 2011).

Photoelectrochemical cell and the factors that affect efficient production of electricity and hydrogen by photocatalytic degradation of (principally) organic and (secondarily) inorganic waste materials are reported by Lianos. Materials used for making a photoanode and the rest of the components of the cell as well as the models of cell efficiency and photodegradation procedures during cell operation have been also described (Lianos 2011).

Efficient photochemical systems for environmental remediation can be constituted by a semiconductor and a surface-adsorbed antenna molecule (dyes or other color species). The major advantage of these systems is that they are able to achieve the degradation of organic pollutants by using visible light from the sun as energy and O_2 in the air as the oxidant under ambient conditions (Chen et al. 2010).

Photolysis in Photocatalytic Membrane Reactors

Leonardo Palmisano

Dipartimento di Energia, Ingegneria dell'Informazione e Modelli Matematici (DEIM),
Universite di Palermo, Palermo, Italy

Photolysis is a chemical process which is able to break down molecules into smaller units through the absorption of light. It can be carried out in a device combining also a membrane. Some results obtained in various photocatalytic membrane reactors are summarized in the following.

Some advanced oxidation processes (AOPs) such as Fenton $\text{H}_2\text{O}_2/\text{Fe}^{2+}$, photo-assisted Fenton $\text{UV}/\text{H}_2\text{O}_2/\text{Fe}^{2+}$, UV photolysis, and photo-assisted Fenton like $\text{UV}/\text{O}_2/\text{Fe}^{2+}$ have been tested for the degradation of gemfibrozil (a widely used blood lipid and cholesterol-modifying drug) in aqueous solution in a batch system and then in a membrane reactor (Molinari et al. 2007). A nanofiltration/reverse osmosis type cross-linked polyamide UTC-60 (Toray) membrane (19 cm^2) was used. Gemfibrozil at an initial concentration equal to 5 mg/L was degraded in the batch degradation tests by employing the four

AOPs, but numerous peaks of intermediates were observed by HPLC analyses. Indeed dissolved oxygen concentration (DOC) analyses indicated a poor mineralization in the case of photolysis (3.1 %) and UV/O₂/Fe (10 %), whereas values of 62 % and 24 % were obtained by using photo-assisted Fenton and Fenton AOPs, respectively. Thus, in the membrane reactor, only the Fenton and the photo-assisted Fenton were tested. In the latter case the results showed a drug degradation higher than 92 %, a mineralization higher than 55 %, and a membrane retention of the catalyst in solution higher than 95 %.

The combination of a dialysis membrane and a photochemical reactor into a membrane photoreactor (MPR) to mineralize organic compounds was described by Azrague et al. (2005). A pollutant model (2,4-dihydroxy benzoic acid) was mineralized from turbid waters in the photoreactor by using VUV (vacuum ultraviolet) irradiation (172 nm). A model based on diffusion through the membrane and first-order reaction in the reactor was in good agreement with the experimental data, in a wide range of operating conditions. This “advanced oxidation process” produces high concentrations of hydroxyl radicals and is a good method to mineralize organic compounds.

The membrane efficiency to photodegrade typical water pollutants was evaluated in a continuous flow water purification device, applying UV irradiation on both membrane sides by Romanos et al. (2012). The developed composite NF membranes were highly efficient in the decomposition of methyl orange exhibiting low adsorption-fouling tendency and high water permeability. A chemical vapor deposition (CVD)-based innovative approach was applied with the purpose to develop composite TiO₂ photocatalytic nanofiltration (NF) membranes. The method involved pyrolytic decomposition of titanium tetrakisopropoxide (TTIP) vapor and formation of TiO₂ nanoparticles through homogeneous gas-phase reactions and aggregation of the produced intermediate species. The grown nanoparticles are diffused and deposited on the surface of gamma-alumina NF membrane tubes. The CVD reactor allowed for online monitoring

of the carrier gas permeability during the treatment, providing a first insight on the pore efficiency and thickness of the formed photocatalytic layers. In addition the thin TiO₂ deposits were developed on both membrane sides without sacrificing the high yield rates. Important innovation was also introduced in what concerns the photocatalytic performance evaluation.

Fulvic acids were removed from model solutions by catalysis, photolysis, and photocatalysis, as well as in the integrated process of photocatalysis and ultrafiltration (Rajca et al. 2011). Experiments were carried out in the Heraeus reactor, where model water of an approximately 10 g/m³ content of fulvic acids was treated. TiO₂ was used as a photocatalyst. The efficiency of fulvic acid oxidation, measured in terms of dissolved organic carbon content and UV absorbance ($\lambda = 254$ nm), was related to the pH of the water (3.5, 7.0 and 10.0) and to the catalyst dose applied (100–600 gTiO₂/m³). The results indicated the efficiency of the photocatalytic process for fulvic acid removal from water and the usefulness of the ultrafiltration membrane in the recovery of the catalyst used. The values of the reaction rate constant and the halftime of fulvic acid degradation were determined using a kinetic model based on a first-order reaction. Relations between rate constant, pH, and photocatalyst concentration in the reaction environment were found.

Photooxygenation

Leonardo Palmisano

Dipartimento di Energia, Ingegneria
dell'Informazione e Modelli Matematici (DEIM),
Università di Palermo, Palermo, Italy

The combination of molecular oxygen (also from air) and light for carrying out chemical conversions is named photo-oxygenation. In the following some applications of this method, involving also membranes, are described.

Synthesis of a series of porphyrin-functionalized pyrimidine dendrimers was accomplished by a procedure involving the nucleophilic aromatic substitution (NAS) as a key reaction step by Chavan et al. (2005). The resulting dendritic porphyrin catalysts showed high activity in the light-induced generation of singlet oxygen ($^1\text{O}_2$) from ground-state oxygen. These materials were synthetically useful photosensitizers for oxidation of various olefinic compounds to the corresponding allylic hydroperoxides. Catalytic activities and regio- and stereoselectivities of the dendritic photosensitizers were comparable to those observed for mononuclear porphyrin catalysts. Recycling of the dendrimer-enlarged homogeneous photocatalysts was possible by using a solvent-resistant nanofiltration (SRNF) membrane (oxidatively stable) consisting of a polysiloxane polymer and ultrastable Y zeolite as inorganic filler. Moreover, this membrane technology provided a safe way to isolate the hydroperoxide products under very mild conditions. The membrane showed high retention for the macromolecular catalysts, even in chlorinated solvents, but some oxidative degradation of the porphyrin units of the dendrimer was observed over multiple catalytic runs.

New heterogeneous photocatalytic membranes for oxidation of organic substrates under oxygen atmosphere at 25 °C were prepared by Bonchio et al. (2006) by incorporating decatungstate in polymeric membranes. Polymeric films with a high thermal, chemical, and mechanical stability (PVDF, PDMS, Hyflon) were obtained. The photocatalyst integrity within the polymeric

support was assessed by using various surface techniques including transmittance and reflectance UV-Vis and FT-IR spectroscopies. Catalyst screening was performed under both homogeneous and heterogeneous photo-oxygenation conditions. The photocatalyst activity was evaluated in terms of substrate conversion, turnover numbers, and recycling experiments. A membrane-induced selectivity behavior was evidenced by comparing heterogeneous and homogeneous oxidations.

Photo-oxygenation process using cholesterol (Ch), an important target for oxidative degradation in cell membranes, is described by Andreu et al. (2008) by taking into account two mechanisms: type I (via free radicals) and type II (mediated by $^1\text{O}_2$). Several dyads have been synthesized from beta- and alpha-Ch and ketoprofen (KP) or tiaprofenic acid (TPA). Upon irradiation under anaerobic conditions, KP-alpha-Ch dyads were efficiently photolyzed, via intramolecular hydrogen abstraction from C-7, whereas KP-beta-Ch, TPA-alpha-Ch, and TPA-beta-Ch remained unchanged after prolonged irradiation. The transient absorption spectra of KP-alpha-Ch were assigned to the short-lived biradicals resulting from intramolecular hydrogen abstraction. Interestingly, the spectra and lifetimes obtained for the TPA-derived dyads were very similar to those of the TPA triplet excited state. For the KP-alpha-Ch dyads, generation of $^1\text{O}_2$ was expectedly negligible. Thus, KP-based dyads are appropriate models for type I Ch oxidation mechanism, whereas the TPA derivatives are suitable systems for investigation of the type II mechanism.

The design of new heterogeneous photo-oxygenation systems able to employ visible light, oxygen, mild temperatures, and solvent with a low environmental impact has been investigated by Drioli et al. (2008). In particular, the heterogenization of decatungstate ($\text{W}_{10}\text{O}_{32}^{4-}$), a polyoxometalate with photocatalytic activity in oxidation reactions, was carried out in polymeric membranes of polyvinylidene fluoride. The polymeric catalytic membranes prepared by phase inversion technique were successfully applied in the aerobic mineralization of phenol (used as a probe pollutant molecule) in water. In order to evaluate the effect of the polymeric environment on the overall catalyst behavior, the decatungstate (opportunistically functionalized) was

heterogenized in perfluorinated membrane made of Hyflon. The photocatalytic composite membranes were characterized by different and tunable properties depending on the nature of the polymeric micro-environment, in which the catalyst was confined. Moreover, the selective separation function of the membrane resulted in enhanced performance in comparison with homogeneous reactions.

Photopolymerization

Haiqing Lin

Department of Chemical and Biological Engineering, University at Buffalo, The State University of New York, Buffalo, NY, USA

Photopolymerization has been widely used to produce photoactive polymer-based systems in the coating industry, paints or printing inks, adhesives,

composite materials, and dental restorative formulations (Roffey 1982; Decker and Moussa 1987; Fouassier 1995; Decker 1996; Andrzejewska 2001). The photopolymerization can occur without solvent and within a fraction of a second when intense illumination is used. More importantly, it occurs only in illuminated areas, thus allowing the generation of high-resolution images for the production of complex patterns such as printing plates, optical discs, and microcircuits (Decker 1996; Andrzejewska 2001; Costner et al. 2009).

Acrylate-based monomers have very high reactivity, and therefore, they are the most widely used for photopolymerization. A typical acrylate monomer is shown below:

where R = H or CH₃ and X = short-chain alkylene, arylene, polyester, polyurethane, polysiloxane (Andrzejewska 2001).

There are two classes of UV photopolymerization, radical polymerization and cationic polymerization. In the radical polymerization, the free radicals (such as benzoyl radicals) are often produced by homolytic cleavage of C–C bonds or by hydrogen abstraction from an H-donor molecule, as shown below (Decker 1996).

In the cationic polymerization, the protonic acids are often generated by photolysis of onium salts in the presence of an H-donor molecule. The

photolysis reaction can be written as below for a sulfonium salt (Degacure K185), producing both Bronsted acids and free radicals (Decker 1996):

where Ph is the phenyl group.

UV photopolymerization is one of the most efficient methods to generate highly cross-linked polymers from multifunctional monomers

(Andrzejewska 2001). Table 1 shows an example UV photopolymerization using acrylate monomers, PEGDA, and PEAMEA (Lin and Freeman 2005; Lin et al. 2006a, b). The benzoyl radicals are

Photoreactor

Raffaele Molinari
Dipartimento di Ingegneria per l'Ambiente e il Territorio e Ingegneria Chimica (DIATIC),
Università della Calabria, Rende, Italy

A photoreactor is a chemical reactor device which brings photons, a photocatalyst, and reactants into

contact, as well as collects the reaction products deriving from physicochemical transformations. It can assume different shapes and modes of operation and can be operated in various environments of temperature and pressure. Design a photoreactor means to establish type, mode of operation, size, and optimal operative conditions. Two general types of photoreactors exist such as batch and plug flow: in the first one, the mixing of reacting mixture is favored as high as possible in order to assume a perfectly mixed reactor, while in the second type, mixing is hindered in order to assume a perfectly segregated reactor. With respect to the operation mode, photoreactors are classified in three general types: (i) discontinuous reactor which during the operation does not exchange matter with the ambient; (ii) semicontinuous reactor which exchanges reagents or products with the ambient; and (iii) continuous reactor, for which there is a continuous and equal inlet and outlet of mass.

The discontinuous reactor is simple and needs only few accessories; it is suitable for experimental kinetics studies, and it is industrially used when the amount of matter to be treated is quite small. The semicontinuous reactor is flexible but more difficult to model; it allows a good control on the reaction rate, as the reaction may be affected by the addition of reagents or by the subtraction of products. The continuous reactor is suitable for industrial purposes when big amount of matter must be treated and/or the reaction rate is extremely high. It needs many accessory devices, but it is possible to achieve a very good control on the product quality (Loddo et al. 2009). The utilization of radiation and solid catalysts in a synergic effect for performing chemical transformations of species present in liquid or gaseous mixtures makes the heterogeneous photocatalytic reactors more complex than the heterogeneous catalytic ones.

The main components of a photocatalytic system are the photoreactor and the radiation. For thermal catalytic processes, the reactor configuration is chosen on the basis of (i) mode of

operation, (ii) phases present in the reactor, (iii) flow characteristics, (iv) needs of heat exchange, and (v) composition and operative conditions of the reacting mixture source (Braun et al. 1991). In addition to previous parameters, the choice of the heterogeneous photoreactors is conditioned by the fact that their geometry and materials must guarantee the penetration of radiation all over the reacting mixture having in mind that the absorbed photon energy should be equal or higher than the bandgap of the used photocatalyst. In the case of stirred photoreactors, the presence of the photocatalyst, usually a powdered micro- or nanocrystalline semiconductor, affects in a complex way the depth of radiation penetration.

Photoreactors and, thus, photocatalytic processes are applicable in wastewater treatment, energy production, chemical synthesis, and greenhouse gas mitigation. They have the potential to address both the consumption of nonrenewable fossil fuels and global warming, two of the greatest problems facing humankind. The state-of-the-art in solar photoreactor design to assess those systems which are most applicable for industrial-scale implementation has been reviewed by Braham and Harris (2009). Designs for parabolic trough, compound parabolic, inclined plate, double-skin sheet, rotating disk, water bell, fiber optic, and fixed/fluidized bed photoreactors are qualitatively discussed and compared. Compound parabolic photoreactors are most suited to near-term applications at pilot scale (>1000 L/day) due to their advantageous light-collecting properties and well-known design methodology.

Engineered photocatalysts, photoreactor systems, process optimizations and modelings of the photooxidation processes for water treatment, and a number of potential and commercial photocatalytic reactor configurations, in particular the photocatalytic membrane reactors, are discussed by Chong et al. (2010). The main technical barrier that impedes commercialization of semiconductor photocatalytic process was the post-recovery of the catalyst particles after water treatment. But, nowadays, membrane photoreactors have shown to solve this drawback (Molinari et al. 2002).

The existence of mass transfer limitations in slurry photocatalytic reactors and experimental validation was made in a flat reactor that was part of a recycling system by Ballari et al. (2010). When the photocatalytic reaction is not fast, employing catalyst loadings below 1 g L^{-1} , irradiation rates at the reactor wall below $1 \times 10^{-6} \text{ Einstein cm}^{-2} \text{ s}^{-1}$, and good mixing operation ($\text{Re} > 1700$), mass transport limitations in the bulk of the fluid can be considered virtually nonexistent.

The photocatalyst with designed physicochemical properties is the key in the process. Recent research progress toward the design and preparation of porous photocatalysts with structural, compositional, and morphological properties suitable for use in a photocatalytic reactor for water treatment via advanced oxidation processes have been reviewed by Pan et al. (2010). Various synthetic strategies for fabricating porous photocatalysts with well-defined microscopic morphologies and nano/mesoscopic active nanobuilding blocks and the synthesis-component-structure-property relationship working in photocatalyst design are discussed.

Physical Cleaning

Barbara Siembida-Lösch

Centre for Alternative Wastewater Treatment,
Fleming College, Lindsay, ON, Canada

Physical cleaning methods generally involve applying hydraulic or mechanical forces to dislodge and remove foulants from the membrane surface. In the course of filtration, diverse phenomena might occur, causing the reduction of the membrane performance. The deposition of solutes and/or particles onto the membrane surface (cake layer formation) or into membrane pores (pore blocking) is one of the main challenges in the operation of membranes, causing flux decrease and/or the increase of the transmembrane pressure (TMP). Whereas physical cleaning can remove reversible fouling, the irreversible one can be only reduced by chemical cleaning. Conventional physical cleaning techniques are based either on hydraulic (forward and reverse flushing, backwashing, membrane relaxation, and air flushing) or mechanical (sponge ball and fluidized particle cleaning) methods. Regarding the cleaning by sponge balls and fluidized particles please refer to mechanical cleaning. Ultrasonic and electrical fields are innovative and emerging cleaning methods that were developed in recent years to overcome the limitations of the commonly used methods and are discussed as nonconventional cleaning strategies. The optimum physical cleaning is closely linked to the nature of fouling.

Conventional Cleaning Methods

Forward and reverse flushing removes foulants by pumping permeate water at high crossflow velocity across the membrane surface facing the retentate side. Because of the more rapid flow and the resulting turbulence, particles absorbed to the membrane are released and discharged. In the reverse flushing method the direction of the permeate flush is alternated for a few seconds in the

forward (feed to brine) and in the reverse direction (brine to feed). Forward flush techniques are particularly useful in removing colloidal matter (Arnal et al. 2011).

Backwashing is a reversed filtration process, in which permeate is flushed through the membrane to the feed side to achieve high shear at the membrane surface. In porous membranes, backward flush results in flushing the pores inside out (Arnal et al. 2011). Periodic backwashing of membranes, usually for a few minutes, at a flux being at least two times higher than the typical filtration flux, is very effective in removing fouling and thus decreasing pressure to the previous low value. Since physical cleaning only removes reversible fouling (Baker 2004), the average pressure still shows a gradual increase with time and chemical cleaning will be necessary to overcome irreversible fouling (Baker 2004). Backwashing is fully automatic, initiated at a fixed interval of operation or once TMP reached a set point (Villarreal et al. 2013). A backwash can only be applied for ceramic, hollow fiber, tube, and some flat sheet ultra- and microfiltration (MF) membranes as backwashing of spiral wound membranes would damage the glue layers of the membrane elements. Backwashing effectiveness depends on the nature of the fouling mechanism it deals with. The more adherent the foulants are, the higher forces are required to minimize fouling (Shi et al. 2014). Although backwashing results in beaks in operation, an increase of energy consumption, and the loss of permeate, it has been widely applied in industry.

Membrane relaxation refers to the periodical break of the filtration process and thus allows concentrated foulants at the membrane surface to diffuse away by diffusive back transport in “relaxed” conditions. Membrane relaxation is suitable for removing reversible fouling only, allowing filtration to be maintained for longer periods before the need for further cleaning. A further enhancement of the process may be ensured by combining relaxation with air scouring, which creates the shear along the membrane removing foulants more effectively (Hong et al. 2002). As opposed to backflushing, this method does not involve the permeate loss; however, it

reduces overall flux, and therefore higher membrane surfaces are needed.

Air flushing (air sparging, air scouring). By using mixture of water and air during membrane cleaning, increased turbulence is achieved that results in high shear forces at the membrane surface improving the removal effectiveness of fouling. Air sparging can be applied either during the course of filtration to reduce fouling deposition or periodically to remove already formed deposits (Cui and Taha 2003; Shi et al. 2014). In ultrafiltration (UF) systems, air is usually introduced periodically into the flushing stream before backwashing takes place. In order to keep filtration process with good productivity, air flushing can be used as a continuous fouling control method, pumping air continuously into the feed stream. Hence, a two-phase flow (gas/liquid) formed parallel to the membrane surface can reduce concentration polarization and control external fouling to some extent (Laborie et al. 1997; Cui and Taha 2003). There are several flow patterns possible depending on the superficial liquid and air velocities; however, slug flow is the most effective pattern to enhance mass flow (Psoch and Schiewer 2006). Air sparging is typically applied in MF and UF membranes, and it seems to work best for tubular and flat sheet membranes and to a lesser extent in hollow fiber and spiral wound modules (Cui and Taha 2003). Parameters such as the type of membrane module, the duration of air flushing, the air velocity, and the size of the air bubbles just to name a few have effects on the cleaning efficiency. The negative side is that compressed air has the potential to cause damage to membranes.

Nonconventional Cleaning Methods

Another method for generating mechanical action is the use of *ultrasound waves* that result in the cavitation of fluids and the consequent increase of turbulence and shear forces on the membrane surface. Frequencies of ultrasound can range between 16 and 1,019 kHz and are generated by electromechanical transducers based on piezoelectric effect. At these high frequencies

cavitation bubbles are promoted by the pass of the ultrasonic waves through the liquid medium in a series of alternate compression and expansion phases promoting their formation, growth, and implosive collapse in the liquid (Arnal et al. 2011). Ultrasound irradiation, caused by the liquid jet, enhances the membrane flux by decreasing the thickness of boundary layer (concentration polarization) and diffusional resistance at the membrane surface (Arnal et al. 2011). According to Wu et al. (2013), while applying an ultrasonic field, also chemical effects happen, i.e., radical species may be formed during cavitation. There are a number of parameters that influence the effectiveness of ultrasound cleaning, i.e., frequency, power intensity, feed properties, membrane properties, crossflow velocity, temperature, and pressure. Some evidence of damage to membranes due to ultrasound irradiation may occur. First, erosion caused by the radicals formed from sonolysis on the membrane surface can be a major concern. Secondly, the ultrasonic cleaning cannot be applied to all membrane materials. Therefore, membrane durability during ultrasound treatment should be taken into account. Despite the considerable potential of ultrasound-induced membrane filtration, the cleaning method has not yet been widely commercialized. The main reasons that this method has been limited up to now are the development stagnation of transducer technology for membrane filtration and the control of membrane erosion (Arnal et al. 2011; Shi et al. 2014).

Pulsed *electric fields* are also used to clean membranes by applying the pulsed fields of a short duration throughout the filtration process on a periodic basis. An electric field is generated by placing two electrodes on either side of a membrane. In some cases only one electrode is used when a membrane itself is made of conductive material, hence acting as an electrode. This cleaning method is very effective at reducing the concentration polarization layer and removing particulate foulants, as the applied electric field can induce charged particles to move away from the membrane surface toward the electrode with the opposite sign. The main mechanism on which the electrical cleaning is based refers to electrophoresis. Besides the occurrence

of electrophoresis, other effects such as electrolysis, Joule heating, or ion migration also happen, which can affect filtration performance and fouling process. The process can be applied for flat sheet and tubular membranes with platinum electrodes. Operation can be applied to crossflow as well as to dead-end configurations (Ahmad and Ibrahim 2002). Electric fields have been also recently applied to membrane bioreactors (MBRs), so-called EMBRs (electric field-attached MBRs). The electric field strength (E) is an important parameter in the operation of electric fields and depends on frequency, feed conductivity, properties of the solutes (concentration, zeta potential, and charge), electrode placement, and material having effect on electric cleaning (Arnal et al. 2011; Shi et al. 2014). Process used to be enhanced by the presence of dynamic turbulence promoters as static metal deployed sheet, oxygen bubbles, or activated alumina in UF membranes (Mameri et al. 1999). As opposed to the conventional physical cleaning strategies, this method involves no significant loss of permeate during the pulse and can be running without interruption. The limitation of this cleaning method is the high energy demand for application of an electric field. The energy consumption could be however kept lower due to the application of the intermittent (pulsed) operation. Moreover, electric fields may also affect biological activities, i.e., through stimulating the secretion of extracellular polymeric substances from cells which contribute to membrane fouling (Von Zumbusch et al. 1998).

Membrane Consultancy Associates Limited,
Reading, RG8 7EJ, UK

Definitions

The term *physical pretreatment* refers to the use of a physical barrier of filtration media to remove particulate contaminants from a liquid phase. In

a pretreatment duty, the media is porous, having a regular structure which can retain particulates while allowing the carrier fluid to flow through the media.

Objectives

The objective of physical pretreatment is to remove particulates which would otherwise foul downstream processes. The specification of the pretreatment media is selected to ensure stable operation for the next treatment stage, which could be, for example, disinfection, reverse osmosis, ion exchange, or an advanced oxidation process.

Description

Physical pretreatment equipment normally falls into one of the following categories:

- Membrane filtration
- Cartridges
- Screens

The characteristic of each of these types of process is that the aperture or media porosity which defines the physical barrier can be precisely controlled to achieve the required level of contaminant removal. For membrane filtration, the aperture would be the size of the pores in the porous media used to create the membrane surface in contact with the feed (Mulder, 1996). For cartridges, the media openings can be created between the strands of material used to make up the media or in the surface porosity of the material chosen. For a screen, the aperture could be determined by the mesh size of the media used or the assembly tolerance of media layers in forming the device.

Granular media filters such as sand filters could also be used to provide a physical filtration barrier. However, granular media filters do not normally achieve a sufficient removal on their own and are therefore often used as part of a more comprehensive treatment train incorporating the use of

chemical preconditioning (see “► [Granular Media Pretreatment Filtration](#)”). Membranes are also sometimes used after a chemical pretreatment stage, but they are just as likely to be used as a simple physical barrier.

Particle Removal Mechanisms

Particle removal in physical pretreatment can be by one of the two mechanisms, i.e., surface removal or depth removal. In a surface removal device, particles are prevented from entering the media due to the fine pore or aperture size at the surface. Particles therefore accumulate at the surface until transported away by bulk fluid flow, or by backwash or cleaning, or by disposal or removal of the media. The capacity of a surface removal mechanism device is relatively low, so the disposal option is unusual. However, it is sometimes used for valuable feedstreams or where there is a very low particle challenge, for example, ensuring that an ultrapure water loop remains particle-free.

A successful surface removal device needs to have an extensive surface and/or an effective cleaning or particle removal mechanism. The part of the media below the surface provides mechanical support and is normally relatively thin and porous so that it does not create an unnecessary resistance to flow. It is important for this type of device that the media surface has a consistent pore or aperture size (i.e., a narrow pore size distribution or consistent mesh structure). Below the surface, any supporting structure needs to confer sufficient strength to ensure robustness and long-term integrity of the separating layer. Membranes and screens use the surface removal mechanism.

The other separation mechanism used in physical pretreatment devices is depth removal. A depth removal device operates by allowing a proportion of the particle challenge from the feed to pass through the media. Particles are then captured within the media structure rather than being retained at its surface. The advantage of this mechanism is that the particle loading of the media is much greater than for a surface filtration

Pore Size, μm	0.001		0.01		0.1		1		10		100	
Approx equiv MWCO, kDa	2-5		100		500-1000

Membrane Technology	RO		Process UF	UF	MBR		Nominal Cartridge		Screens			
		NF			MF		Sterilizing Cartridge		Granular media filters			

Physical Pretreatment, Fig. 1 The filtration spectrum for physical pretreatment

device. The disadvantage is that the device cannot be relied on to remove all of the target particles since having entered the bulk of the media, they may evade all potential capture sites. Also, it may be difficult to remove the particles once captured. It is quite common therefore to dispose of the media when fully loaded rather than try to clean or regenerate it. Cartridges often use the depth removal mechanism.

Membrane Filtration Products

The separation spectrum for filtration devices is illustrated in Fig. 1. The term membrane filtration is used to describe the processes of ultrafiltration (UF) and microfiltration (MF) (Zeman & Zydney, 1996). UF membrane normally used for pretreatment have a pore size of around 0.01–0.02 μm , though finer UF is also used for process duties. The MF pore size for pretreatment normally ranges from 0.04 to 0.1 μm , though there are coarser MF membranes for other duties. Below the size range of UF is the membrane process nanofiltration (NF) with a pore size of around 0.001 μm or 1 nm. This can be used for pretreatment, but is more likely to be the recipient of a UF or MF pretreated feedstream. However, the most common process following membrane pretreatment is reverse osmosis (RO), since this technology is particularly sensitive to particulate fouling due to the characteristics of the spiral wound element format often used.

UF membranes often use a hollow fiber format with a polymeric membrane material having an

asymmetric structure. A fine porous surface or active separation layer is supported by a more porous open structure, as shown in Fig. 2. In MF, the pore structure through the wall is symmetric or with limited asymmetry. This ensures that the fiber has sufficient strength when differential pressure is applied to drive flow through the structure. Ceramic materials are also used for UF and MF in process duties, and recently there has been an uptake of ceramics for water applications.

Cartridge Products

Membrane cartridges are made from a porous membrane, potentially cast onto a support medium. Depth cartridges are made by winding a polymer thread or string around a former to create a porous depth network. A supported membrane media for use in a membrane cartridge is shown in Fig. 3.

This type of cartridge provides an absolute filtration barrier like a membrane filtration process. Since membrane cartridges are normally difficult to clean, they are used for feeds with a low solid loading.

The thread or string wound depth cartridge provides a nominal removal rating and is utilized for noncritical duties. A nominally rated cartridge is often used for very good consistent feeds to provide a minimal filtration duty prior to RO or other advanced treatment. This type of cartridge is also used after other pretreatment processes to provide an inexpensive guard duty in case of breakthrough, equipment failure, or unexpected

contamination. Since most cartridges are not cleanable, they tend to be only used for duties in which the solid loading is expected to be low.

Backwashable cartridges can be used, and there are various proprietary devices in use. However, it is not common to find them used for pretreatment applications.

Screen Products

In the context of physical pretreatment, screens are used as a preliminary pretreatment stage, often providing protection to other pretreatment devices. It is common to use screens as a pretreatment to membrane filtration, since membrane products have a limit as to the size of

particle that can be accepted in the feed. The nominal rating for a screen in this type of duty is typically between 50 and 300 μm. Screens are not normally used for other filtration devices such as granular media filters, since this same limit to the influent feed quality does not apply.

The simplest screens are formed from wire mesh. The media is cleanable and can use either an automatic backwash mechanism or could be cleaned manually in situ, or the media could be removable for manual backwash. Since the mechanism is that of surface filtration, the dirt holding capacity is not that great; hence, cleaning is relatively frequent if there is a significant feed challenge.

Coarse screens may use a different media, and an example is the bar screen used for membrane

bioreactor pretreatment, which requires a rating of 0.3 mm or higher.

At the finer end of the spectrum, it is possible to get screens with a fine rating of 20 μm or even less. However, it would be unlikely that this rating would be fine enough for direct pretreatment to RO and would be unnecessarily fine for a preliminary stage prior to membrane pretreatment.

Fouling Mechanisms

Particle removal technologies are prone to fouling by the challenge that they are trying to remove (Pearce, 2011). A simplified representation of the two main physical fouling mechanisms is shown in Fig. 4. If the pore or aperture openings of the media are larger than the particles that are being removed from the feed, they may enter the throat of the pore and block the pore from contributing to flow. The second mechanism shows a high concentration of particles of different sizes congregating near the pore openings and causing a cake layer to build up. As the cake layer develops, it effectively becomes the filtration medium since it prevents particles approaching the surface.

For physical pretreatment devices that rely on a surface filtration mechanism, the openings of the media (i.e., the mean pore size and the pore size distribution) have to be carefully selected to avoid the pore blocking phenomenon, also known as pore plugging. Thus, for water treatment applications in which there is a low solid loading but a high concentration of fine particles, an ultrafiltration (UF) membrane might give a more stable

performance than microfiltration (MF). In wastewater, which has a higher concentration of larger particles and the presence of floc particles, MF is often selected. The process design required to prevent the accumulation of solids at or near the surface is discussed in the next section.

The consequence of fouling is that the differential pressure rises if flow is maintained, either due to the restriction in the number of pores available or due to the additional resistance for the feed to transfer across the developing cake layer or a combination of both. As fouling progresses, there comes a point at which differential pressure rises sharply, which indicates that the useful productive cycle is at an end. Increasing pressure under these conditions can force particles further into the pores and/or cause the cake layer to compress becoming less permeable, and both of these effects can be difficult to reverse in the cleaning cycle.

For a device which operates by a depth filtration mechanism, the media is selected to ensure that particles can penetrate the surface, so that they can subsequently be captured in the depth of the bed, thereby ensuring a high dirt holding capacity. If the particle concentration is excessive for the media pore size selected, a cake will form on the surface, significantly reducing the life of the filter. This phenomenon is referred to as surface blinding, since there is normally no mechanism employed to control the effect or reverse it if it happens.

Process Design for Surface Removal Devices

Physical Pretreatment, Fig. 4 Particle fouling mechanisms

Membranes and screens are the two most common types of device that use a surface removal mechanism. There are two possible process designs for their operation, and they will be illustrated in this section by reference to normal process design terminology and operating parameters encountered in membranes. For membrane systems, the two process design options are referred to as either crossflow or dead end with backwash, sometimes known as directflow. In crossflow, the carrier fluid sweeps across the surface of the media, preventing

Physical Pretreatment,
Fig. 5 Crossflow process
 flow scheme

Physical Pretreatment,
Fig. 6 Directflow process
 flow scheme

an excessive accumulation of particles, as shown in Fig. 5. If possible, it is desirable to use a velocity high enough to create some degree of turbulence, but in practice, the feed channel dimensions for water treatment products are often too narrow for that to be practical without an excessive pressure loss on the feed side. A narrow feed channel gives a high packing density, which reduces capital cost for high flow applications.

The bulk carrier fluid passes through the media to provide a particle-free filtrate on the other side. The disadvantage of crossflow is that even at modest velocities, the energy cost is prohibitive for many applications, particularly in water and wastewater treatment. An alternative approach is to use a directflow process flow scheme as shown

in Fig. 6. Directflow is suitable for feed streams that do not contain an excessive concentration of solids, and this applies to most feeds in the water and wastewater industry. It is possible to use this approach for feeds containing 100 ppm of total suspended solids or more, but most duties for which this approach is used have less than 10 ppm.

Feed is passed into the feed channel during a filtration cycle, which typically lasts for 20–60 min. For a hollow fiber membrane, the feed channel can either be inside the fiber lumen (known as the inside feed format) with filtrate withdrawn through the shell or module housing. Alternatively, the feed can be on the outside or shell side of the fiber (the outside feed format) with filtrate withdrawn from the lumen. For either

format, the process sequence has similarities. Particles are retained within the feed channel, accumulating at the dead end, which is a closed valve, signified in red. As with crossflow, the bulk carrier fluid passes through the membrane to provide a particle-free filtrate.

Periodically, a short backwash or cleaning cycle then takes place which removes the accumulated solids from the surface. The cleaning cycle may be assisted by air for the outside feed format and in some cases is conducted by draining fluid from the feed channel while applying an air scour. At the end of the cleaning cycle, which is normally complete in a minute or less, feed flow is reintroduced to the feed channel and a new filtration cycle begins. The concentrated backwash constitutes a waste stream which might be reprocessed to enhance recovery.

The process design for the operation of screens is normally dead end with backwash. Particles retained by the media in the filtration cycle are then removed by a high pressure reverse flow to ensure that they are flushed out on the media effectively in a short backwash cycle.

Process Design for Depth Devices

A depth filtration device such as a cartridge operates like a dead end or directflow process, but without backwash. The dirt holding capacity is sufficient to allow the cartridge to operate for a reasonable length of time until the capacity is exhausted. The cartridge is then removed and replaced. It is possible with some cartridges to remove and clean the media, but normally they are disposed of. If the cartridge is performing a guard duty, the economics of disposal are acceptable since the loading is low, but feed upsets can cause excessive replacement.

It is important to choose the correct rating and type of cartridge since the particles should not bridge the pores at the surface, but penetrate the depth, or the extensive dirt holding capacity provided by the depth of media will not be utilized and cartridge life will be short. However, if the pore size selected is too open, fine particles will contaminate the filtrate, which

might mean that the pretreatment duty is not performed effectively.

Physically Irreversible Fouling

Pierre Le-Clech

School of Chemical Engineering, The University of New South Wales, UNESCO Centre for Membrane Science and Technology, Sydney, NSW, Australia

Antonyms

► [Physically reversible fouling](#)

Physical cleaning of the membrane (e.g., by rinsing, relaxation, backwashing) is generally not able to remove all the fouling materials present on the membrane surface. The fraction of fouling remaining on the membrane surface is defined as physically irreversible fouling. As the level of physically irreversible fouling increases with continuous filtration, the filtration becomes unsustainable, and chemical cleaning is generally conducted in order to remove a greater portion of fouling materials.

Given that physical cleaning is expected to remove more of the large fouling materials having low level of interactions with the membranes, physically irreversible fouling will be due to

smaller compounds able to enter the pores of the membranes or having strong interactions with the membrane polymers. They will include small organic compounds (biopolymeric substances, such as proteins, carbohydrates, humics, and smaller building blocks) and inorganic scales.

Physically Reversible Fouling

Pierre Le-Clech

School of Chemical Engineering, The University of New South Wales, UNESCO Centre for Membrane Science and Technology, Sydney, NSW, Australia

Antonyms

► [Physically irreversible fouling](#)

In order to remove a portion of the fouling formed during membrane filtration, physical cleaning is generally conducted. Strategies including relaxation (during which, filtration is paused for few seconds up to a minute) and backwashing (during which, permeate is pumped in the reverse direction back into the membrane) are commonly applied for low-pressure systems such as microfiltration (MF) and ultrafiltration (UF). Recently, relaxation and osmotic backwash have also been considered for nanofiltration (NF) and reverse osmosis (RO) (Ramon et al. 2013)

In MF and UF, materials responsible for physically reversible fouling are generally large particulate/colloidal compounds, having low degree of interactions with the membrane surface and because of their large size, being easily removable by relaxation and backwashing. During relaxation (and the absence of flux-induced dragging forces), the deposited materials on the surface of the

membrane tend to detach due to the shear rate still applied in the feed bulk. In the case of backwashing, some of the smaller compounds (biopolymers, colloids) entrapped within the pores of the membranes can also be dislodged and pushed back into the feed stream.

Physical cleaning is generally implemented in addition to other continuous fouling control strategies (i.e., operating conditions used to limit the extent of fouling during filtration, including high feed cross flow velocities, aeration, etc.).

Although physical cleanings are used on a frequent basis, their efficiency is known to decrease with filtration time. As irreversible fouling accumulates on the surface, chemical cleanings of various intensities (i.e. higher concentration of the cleaning agent) can be applied on a weekly to yearly basis.

Pineapple Juice, Ultrafiltration of

Carmela Conidi

Institute on Membrane Technology, National Research Council of Italy, ITM–CNR, Rende, Italy

Pineapple is one of the most appreciated tropical fruits due to its very attractive aroma, flavor, and other beneficial components.

Numerous in vitro studies have reported its high antiradical activity and capacity to inhibit the human low-density lipoprotein and liposome oxidation. Biochemical and pharmacological

activities have been attributed to free radical scavenging, effect on immune and inflammatory cell functions, and antitumor properties.

The conventional pineapple juice processing is often accomplished by some drawbacks such as browning, formation of haze/precipitates, and flavor changes which limit the production of high-quality juices. For example, conventional clarification of pineapple juice involves many steps, such as enzymatic treatment (depectinization), cooling, flocculation (gelatine, bentonite, and diatomaceous earth), decantation, and filtration, requiring more costs with personnel, equipment, and physical space.

Ultrafiltration, a pressure-driving membrane process, is considered one of the alternative methods for pineapple juice production.

UF process permits to retain large species such as microorganisms, lipids, proteins, and colloids, while small solutes such as vitamins, salts, and sugars flow with water. The advantages of UF process over conventional pineapple juice clarification are increase of juice yield; possibility to operate in a single step and to reduce working time; reduction in enzyme utilization; easy cleaning and maintenance of equipment; possibility of avoiding the use of gelatines, adsorbents, and other filtration aids; elimination of need for pasteurization; and reduction of waste products. In addition, the UF process, working at room temperature, preserves the natural pineapple fruit constituents, the juice freshness, as well as the volatile aroma profile avoiding the deleterious effect of thermal treatment, such as sugar caramelizing and browning. This process is typically used to separate the pineapple juice into a fibrous concentrated pulp (retentate) and a clarified fraction free of spoilage microorganisms (permeate).

Permeate fluxes and quality of clarified pineapple juice are strongly affected by operating conditions, such as cross-flow velocity, transmembrane pressure, temperature, volume reduction factor (VRF), and membrane properties such as membrane material (polymeric or ceramic) and molecular weight cut-off (MWCO).

Polysulfone and ceramic membranes with a MWCO in the range of 30–100 kDa have been extensively used for pineapple juice UF (de Carvalho et al. 1998; Laorko et al. 2010).

A 100 kDa PS membrane permitted a good level of clarification of pineapple juice reducing totally the suspended solids and the turbidity of the juices. The clarified pineapple juice presented physicochemical and nutritional properties comparable with those of fresh fruits in terms of vitamin C, total phenolic content, and antioxidant activities.

A major limiting factor in pineapple juice UF processes is the declining permeate flux (J) with time (t) reducing process efficiency. This decrease is caused by the accumulation of macromolecular or colloidal species (such as pectin material, tannins, protein, and fiber) on the membrane surface (concentration polarization and gel layer) or the possible precipitation of smaller solutes in the membrane pores (fouling).

The complete pore blocking and cake formation are the main mechanisms involved in the UF of pineapple juice with ceramic tubular membranes and polysulfone hollow fiber membranes, respectively (de Barros et al. 2003).

The clarified pineapple juice can be used in the manufacture of different products such as liqueurs, cocktails, fizzy beverages, and flavored mineral water. Moreover, the bioactive compounds present in the permeate fraction may be used in the pharmaceutical and food industries for the production of nutraceutical and as food formulations. The clarified pineapple juice can be submitted to a concentration step by using thermal evaporation or membrane operations such as reverse osmosis (RO), osmotic distillation (OD), and membrane distillation (MD).

Plasma Etching

Stephanie Roualdes

IEM/UM II – CC 047, Place Eugene Bataillon,
Montpellier, France

Plasma etching (Yasuda 1985; d'Agostino 1990; Biederman and Osada 1992; Inagaki 1996) is one of the major effects caused by the interaction between a cold plasma (defined in the article entitled "Vapor plasma membrane treatment") and a material placed within it. It is due to combination of reactive species of the gas phase with atoms or groups of atoms of the substrate leading to the creation of active sites on the surface of the substrate (ablation of surface) and to the formation of volatile species which diffuse in the gas phase. Plasma etching is prevalent on the other plasma treatments (plasma functionalization, PECVD/plasma polymerization) in the case of inert gases such as rare gases (argon (Ar), helium (He)), O₂, SF₆, or C_xF_y used as gaseous phases.

Plasma etching is mainly used for the surface modification of polymers or metals. In the case of a polymeric substrate, plasma etching is systematically coupled with substrate cross-linking due to opening (under the action of the reactive species of plasma) of the bonds between atoms of the surface of the substrate allowing them to reorganize (by bridging between the macromolecular chains). The main application of plasma etching is certainly the preparation of MEMs in microelectronics. In the field of membranes, the implementation of plasma etching has appeared in the last decade. Plasma etching has been applied for modulating the membrane transport properties (by cross-linking the surface chains, increasing the pore size, or etching the polluted surface) or reinforcing their mechanical, thermal, and chemical stability (essentially under the effect of cross-linking) (Bryjak et al. 1996; Gancarz et al. 1999; Reinholdt et al. 2012). However, it is generally known that, in the case of some specific polymer membranes, the effect gained in such modifications may disappear or significantly diminish during storage. Moreover, plasma etching can

sometimes alter the physicochemical properties of material and particularly polymer surfaces.

Plasma Functionalization

Stephanie Roualdes

IEM/UM II – CC 047, Place Eugene Bataillon,
Montpellier, France

Plasma functionalization (Yasuda 1985; d'Agostino 1990; Biederman and Osada 1992; Inagaki 1996) is one of the major effects caused by the interaction between a cold plasma (defined in the article entitled "Vapor plasma membrane treatment") and a material placed within it. It is due to fixing of reactive species of the gas phase on active sites of the surface of the substrate. Plasma functionalization is prevalent on the other plasma treatments (plasma etching, PECVD/plasma polymerization) in the case of chemically reactive gases such as ammonia (NH₃), nitrogen (N₂), oxygen (O₂), carbon dioxide (CO₂), water vapor (H₂O), tetrafluoromethane

(CF₄) . . . used as gaseous phases. More precisely, plasma functionalization consists in grafting of amine-type or amide-type functional groups in the case of NH₃ or N₂, grafting of peroxide or hydroxide functions in the case of O₂ or H₂O, grafting of C=O, C-OH, C(=O)OH functions in the case of CO₂, and grafting of CF_x functions in the case of CF₄. In the case of a polymeric substrate, plasma functionalization is systematically coupled with substrate cross-linking due to opening (under the action of the reactive species of plasma) of the bonds between atoms of the surface of the substrate allowing them to reorganize (by bridging between the macromolecular chains).

Plasma functionalization is mainly used for the surface modification of polymers or metals. In the field of membranes, the implementation of plasma functionalization has grown rapidly in the last decade. Plasma functionalization has been especially applied for improving the wettability, printability, adhesion, or biocompatibility of conventional polymer membranes, modulating their transport properties (by changing the hydrophilic/hydrophobic balance, providing the grafting of specific functional groups or cross-linking the surface chains), or reinforcing their mechanical, thermal, and chemical stability (essentially under the effect of cross-linking) (Roualdes et al. 2010).

However, it is generally known that, in the case of some specific polymer membranes, the effect gained in such modifications may disappear or significantly diminish during storage. Moreover, plasma functionalization can sometimes alter the physicochemical properties of material and particularly polymer surfaces. An efficient way to overcome this limitation is the implementation of a process named plasma-induced graft polymerization or plasma grafting. In this process, plasma is used only to create on the polymer surface functionalities that are able to initiate conventional polymerization of monomers containing multiple bonds. The reaction may be carried out in two ways: in the vapor phase of monomer or in solution. Its principle is the following. Plasma treatment can induce radical formation on polymers surface through ion bombardment and UV

radiation. The radicals formed on the surface of the treated polymers can be very stable in vacuum but react rapidly on exposure to a reactive gas. So if the vapor phase of an unsaturated monomer is introduced into a plasma reactor just after the surface treatment of a polymer substrate, the radicals formed on the surface of the polymer substrate immediately cause the polymerization of the monomer. The process can also be implemented in solution. In this case, the polymer substrate is released from the reactor after the plasma treatment and then exposed to atmosphere. In the presence of oxygen or air, peroxides and hydroperoxides are created on the polymer surface; such functions may initiate the polymerization of a desired monomer in solution. In both cases (vapor phase route or solution route), grafting density and length of grafted brush can be regulated to some extent by plasma and grafting parameters. One primary advantage of this technique is the ability to modify surface properties of the polymer substrates permanently without affecting the bulk mechanical and chemical properties. There have been several reports on hydrophilization of polysulfone surface after plasma treatment by plasma-induced graft polymerization (Inagaki et al. 1997; Muller et Oehr 1999; Liu et al. 2005).

Plasma Membrane

Stephanie Roualdes
IEM/UM II – CC 047, Place Eugene Bataillon,
Montpellier, France

Plasma membrane names either a conventional membrane which has been modified on the surface by a plasma treatment (plasma etching, plasma functionalization, PECVD/plasma polymerization), called plasma-treated membrane, or a plasma polymer deposited on a highly porous substrate (which plays the role of mechanical support) having specific separation properties, called plasma-polymerized membrane (see article “plasma polymerized membrane” for more details).

The first developed plasma membranes have been intended to gas permeation or retention and also pervaporation. As a striking example relative to plasma-treated membrane for gas permeation, Kumazawa et al. studied the gas perm-selectivity of polyethylene (Nakata and Kumazawa 2006) and polypropylene (Teramae and Kumazawa 2007) membranes after a 5 min long N₂ or NH₃ plasma treatment. They found that nitrogen was not significantly incorporated to the polymer network and that CO₂ permeability coefficients slightly increased after the plasma treatment, whereas N₂ ones were not affected, which places these plasma-treated polymer membranes over classical glassy polymers like polyimides, in terms of CO₂ separation factor. Vilani et al. (2007; Weibel et al. 2007) studied polyurethanes membranes used to separate methanol from methyl-t-butyl ether by pervaporation after an acrylic acid vapor plasma treatment. They

showed that a short-time modification with a high plasma input power (100 W) allowed to increase the selectivity factor from 5 to 30 and also the permeate flux (Vilani et al. 2007). They attributed these evolutions to an increase of C=C contribution and a loss of C–N content that might result in a cross-linking at the surface due to decreases of the surface-free volume and chain flexibility. Upadhyay and Bhat (2004) proved the strong efficiency of a nitrogen plasma treatment compared to oxygen or air plasma treatments of nonporous polyvinyl alcohol-based membranes. The extremely high selectivity of the nitrogen-treated membranes toward water molecules (over 1,200 in isopropyl alcohol (IPA) – water mixture with IPA weight fraction below 0.8) could be attributed to the surface cross-linking, whereas air and oxygen plasma-etched amorphous regions decrease the swelling of the treated membranes and their selectivity to water.

More recently, plasma membranes have been prepared for liquid separation processes. A lot of works have been devoted to polysulfone (PSU) membranes widely used in microfiltration or ultrafiltration processes, in particular for low-protein adsorption in serums and plasma. There have been several reports on hydrophilization of PSU surface after plasma treatment by noncondensable gases, plasma-induced graft polymerization, or plasma polymerization (Roualdes et al. 2010). Selective membranes for the separation of water from hydrophobic liquids can be obtained by depositing a hydrophobic plasma-polymerized thin layer on porous materials such as filter paper or polyester textile (Bankovic et al. 2004). The development of plasma membranes has been more recently applied to fields using ion-conducting membranes such as electromembrane processes (electrodialysis in particular), electrochemical sensors, or, more broadly, the energy production devices (fuel cells, Li-ion batteries, etc.) (Roualdes et al. 2010).

Plasma Polymerization

Stephanie Roualdes
IEM/UM II – CC 047, Place Eugene Bataillon,
Montpellier, France

Plasma polymerization is the other name of PECVD in the case of vapors of organic compounds as gaseous phases (the most case in the field of membranes). Plasma polymerization has little in common with classical polymerization. Many side reactions occur during film deposition. This can be understood by the poor selectivity of the breaking up of chemical bonds in a plasma. The mechanism of deposition is not yet well understood. This difficulty arises from the complexity and variety of active species, reaction steps, and dependences on plasma parameters. Several kinetic models of plasma polymerization have been proposed. The most popular are the

models of Lam et al. (1976), Poll et al. (1976), and Yasuda (1985). These models involve a competitive ablation and polymerization (CAP) mechanism which gives an account of the rather complicated and interrelated influences of fragmented elements in the deposition of plasma polymers. It is important to mention that chain-growth polymerization cannot occur under vacuum. This is simply because there are too many chain-carrying species but not enough monomer with a well-defined chemical structure capable of chain-growth polymerization. With the occurrence of fragmentation of the monomer structure, the situation becomes even worse. The way in which a plasma polymer is formed in plasma has been explained by the rapid step-growth polymerization mechanism. The essential elementary reactions are stepwise recombination of reactive species (free radicals) and stepwise addition or intrusion via hydrogen abstraction by impinging free radicals. It is important to recognize that these elementary reactions are essentially oligomerization reactions that do not form polymers by themselves. To form a polymeric deposition, a certain number of steps must be repeated at the surface. As the plasma polymerization proceeds, the activated species may attack the growing polymer layer. This attack can decompose the polymer, extend the cross-linking of the polymer, or cause the elimination of deposited polymer (ablation process). These polymerization and ablation processes proceed competitively, and the overall plasma deposition rate is dependent on the plasma polymerization parameters.

Plasma polymers, noted PP-X (X being the monomer), are not formed by the repetition of a monomer unit like classical polymers. They are disorganized thin films, with short and branched chains (randomly terminated with frequent cross-links) often not reminding the monomers they come from. In terms of material properties, plasma polymers present a great number of advantages when compared to films synthesized, on the one hand by other techniques of vacuum deposition, on the other hand by liquid-route synthesis methods (see article entitled “PECVD”).

The microstructural properties of plasma polymers depend mostly on the parameters of plasma

polymerization and more particularly on the W/FM parameter. In the monomer-sufficient region (low W/FM values), monomer molecules are subjected to less fragmentation to be plasma polymerized, and plasma polymers with less arrangement and small loss of some groups such as hydrogen, methyl, hydroxyl, and carbonyl groups are formed. Under such soft synthesis conditions, plasma polymerization retains more the molecular structure of the monomer; plasma polymers are more organic and less highly cross-linked and thus resemble more conventional polymers; they are said to be polymer-like materials. In the monomer-deficient region (high W/FM values), monomer molecules are subjected to heavier fragmentation, and plasma polymers with much more rearrangements and a larger loss of some groups (especially carbon-based ones) are formed. Under such drastic synthesis conditions, plasma polymers are harder, more inorganic, and more highly cross-linked; they are said to be ceramic-like. For intermediate values of W/FM, a wide range of hybrid materials can be manufactured. Let us consider the case of hexamethyldisiloxane (HMDSO), widely used as monomer in plasma polymerization (Ayril et al. 2008). In soft plasma conditions, the plasma film synthesized from HMDSO has a structure close to those of the HMDSO monomer and also the polydimethylsiloxane (PDMS), which is the closest conventional polymer, as shown by Fourier transform infrared (FTIR) spectroscopy; this plasma film is thus called PDMS-like plasma polymer; its density is quite low, equal to 1.1. In hard plasma conditions, the obtained plasma film is similar to amorphous hydrogenated silica with a density of 2.2; it is noted a-SiO₂:H ("a" for amorphous, ":H" for hydrogenated); the dilution with an oxidative gas as O₂ or N₂O in the plasma reactor can enable to achieve this silica structure at lower W/F values. Mass spectrometry (MS) is a very useful technique to reveal the low fragmentation of the monomer in soft plasma conditions and, on the contrary, the formation of many light species due to strong fragmentation in highly energetic plasmas.

Although considered as dense materials, plasma polymers are characterized by a free

volume comparable to ultramicroporosity (spaces between chains lower than 0.7 nm). Changing the plasma parameters in the preparation of films can enable to tune this free volume as well as the chains flexibility. The approaches that may achieve enhanced free volume and chain flexibility can be summarized as follows: (1) minimization of the W/FM parameter, (2) pulsing of the RF field to reduce the plasma-on time, (3) use of a Faraday cage around the substrate, (4) positioning the sample downstream from the plasma zone (post-discharge configuration), (5) use of monomers containing polymerizable double bonds, and (6) use of a cold substrate. It is possible to further increase the free volume and change it into micro- (pores diameter between 0.7 and 2 nm) or meso- (pores diameter of some nanometers) porosity by adding a porogen in the plasma reactor as comonomer and then eliminating it from the prepared film by thermal or UV posttreatment (Favenec et al. 2004; Rouessac et al. 2006). The porogen approach is mainly applied to polymer-like plasma films. Indeed, ceramic-like plasma materials are usually required for their highly dense structure; nevertheless, they sometimes naturally contain some microporosity because of chain breakings due to very high cross-linking degrees (Roualdes et al. 2002).

For membrane applications, plasma polymerization is usually performed on a highly porous substrate whose only role is to mechanically support the thin plasma polymer, called plasma-polymerized membrane in this case. Nevertheless, plasma polymerization can also be applied on a dense or poorly porous substrate being already an active membrane; in this case, it could achieve the same effect as plasma etching or plasma functionalization (i.e., modification of surface characteristics of the membrane substrate) with additional advantageous characteristic features of the nanometer film of plasma polymer. Moreover, a special kind of plasma polymerization that has received increased attention in recent years is the preparation of plasma polymers by radio-frequency sputtering from polymeric targets. Most attention is paid to fluorocarbon plasma polymer films sputtered from polytetrafluoroethylene (PTFE) using magnetrons

(Finsterwalder and Hambitzer 2001). The main advantage of this innovating process is that the deposition rate and the organization of the chains of the material structure are much higher than in the case of classical plasma polymers. While the activation mechanism is very different from that of the classical plasma polymerization, the deposition mechanism is not.

Plasma Polymerized Membrane

Stephanie Roualdes
IEM/UM II – CC 047, Place Eugene Bataillon,
Montpellier, France

Plasma-polymerized membrane names a plasma polymer deposited on a highly porous substrate

(which plays the role of mechanical support) having specific separation properties.

The high degree of flexibility in free volume and chemical structure of plasma-polymerized membrane (see entry “► [Plasma Polymerization](#)”) makes them good candidates as membrane materials. Plasma polymers have been used as membrane materials since the 1980s; the first reported study was from Yasuda (Yasuda 1984). Their main advantages in such an application field are their high cross-linking degree giving them high separation efficiency as well as high chemical and thermal stabilities and their small and easily tunable thickness enabling a modulation of their permeation ability. As plasma polymers are not self-supported, they must be deposited onto symmetric or asymmetric support with a surface pore size and a surface roughness that should be in agreement with the deposited thickness. This support primarily acts as a mechanical support. The plasma polymerization technique cannot deposit thin films on the pore walls inside porous substrates like it can be done by counter diffusion CVD, but plasma polymerization is able to modify the mouth of the pores at the surface of substrates, especially if the latter is macroporous (pores diameter above 50 nm). In that case, the final membrane properties depend both on the plasma polymer and on the starting support as the applied plasma polymerization process duration is not enough to make a complete and homogeneous layer. In the case of a complete homogeneous layer, the transport properties will be mainly governed by the intrinsic separation properties of the plasma polymer.

The first developed plasma-polymerized membranes have been intended to gas permeation or retention (Inagaki and Tsutsumi 1986; Inagaki et al. 1990; Roualdes et al. 2002; Julbe et al. 2008) and also pervaporation; more recently, plasma-polymerized membranes have been prepared for liquid separation processes (nanofiltration and ultrafiltration essentially) (Roualdes et al. 2010). For gas or liquid separation, membranes providing high fluxes of penetrants are required. Polymer-like plasma films are more suitable in this case. If the plasma film does not totally plug the porosity of its support, the

transport properties across the membrane will be controlled by the viscous flow. If the plasma film constitutes a complete homogeneous layer at the surface of its support, the transport properties of the membrane will be mainly governed by the solution diffusion, microporous surface diffusion, or molecular sieving mechanisms inherent to the plasma polymer. Being highly cross-linked in essence, polymer-like plasma materials are generally not as permeable as conventional membranes. In order to enhance their permeability, the easiest solution consists in reducing their thickness, to the detriment of their mechanical stability. Another solution is to increase their free volume and/or chain flexibility to make them resemble more conventional polymers. For gas retention (packaging application essentially), membranes providing low fluxes of penetrants are required. Ceramic-like plasma films are more suitable in this case; their transport properties are rather controlled by the molecular sieve mechanism as for classical crystallized ceramics.

The development of polymer-like plasma films has been more recently applied to fields using ion-conducting membranes such as electromembrane processes (electrodialysis in particular), electrochemical sensors, or, more broadly, the energy production devices (fuel cells, Li-ion batteries, etc.) (Roualdes et al. 2010). Such applications require the use of materials having a good swelling in water and containing specific functions, often charged, distributed in an ordered manner in order to form effective channels of ionic conduction. Obtaining such materials by plasma polymerization is particularly challenging and requires a delicate research task in the choice of the precursor (s) and the adjustment of plasma parameters.

Plasma Polymers (PPs)

Tauqir A. Sherazi

Department of Chemistry, COMSATS Institute of Information Technology, Abbottabad, Pakistan

The term plasma polymer represents a material that is created as a result of a passage of monomer in gaseous form through the glow discharge (Oadian 2004), or simply one should say that an electric discharge in an organic gas produces plasma polymer. Usually, it is deposited in the form of a thin film. Plasma polymers are different from the conventional polymers. In general, conventional polymer has regularly repeating units (Fig. 1), while in the case of plasma polymers, a great number of free radicals are trapped within the network; because of these radicals, the chains are short, and in addition they are randomly branched and terminated with a high degree of cross-linking (Fig. 2).

The application of plasma causes the generation of a great number of free radicals which are trapped within the plasma polymer network. These radicals cannot recombine rapidly, and

Plasma Polymers (PPs), Fig. 1 High density polyethylene (HDPE), an example of conventional polymer

Plasma Polymers (PPs), Fig. 2 Hypothetical structure of a hydrocarbon plasma polymer (Biederman 2004)

therefore when the plasma polymer is exposed to the open atmosphere, they react with the oxygen and water vapor. These free radicals are the cause of often observed aging processes in plasma polymers. Plasma polymers possess a rather disordered structure, and this depends on the intensity and energy of the species bombarding the growing film.

Applications

The advantages of plasma polymer films include excellent coating adhesion on almost all substrates (Feddes et al. 2004), chemical and mechanical stability (Hamerli et al. 2003), thermal stability (Zhang et al. 2003), and high barrier effects (Moffitt et al. 2000). Applications of plasma-polymerized films are associated with biomaterials, textile industry, electronics (e.g., semiconductors, insulators, thin-film dielectrics), optical applications, chemical processing (reverse osmosis membrane, permselective membrane), and surface modification (adhesive improvement, protective coating). A significant area of research has been on the use of plasma polymer films as permeation membranes. The permeability characteristics of plasma polymers deposited on porous substrates are different than usual polymer films. The characteristics depend on the deposition and polymerization mechanism. Plasma polymers as membranes for separation of oxygen and nitrogen, ethanol and water, and water vapor permeation have all been studied (Inagaki 1996). The application of plasma-polymerized

thin films as reverse osmosis membranes has received considerable attention as well (Kim and Kim 2001).

Plasma-Enhanced Chemical Vapor Deposition

Antonella Milella and Fabio Palumbo
Department of Chemistry, University of Bari
“Aldo Moro”, Institute of Nanotechnology
(CNR-NANOTEC), Bari, Italy

Plasma-enhanced chemical vapor deposition (PECVD) is a process of film formation onto a substrate when a plasma is applied to a proper vapor or gas precursor. PECVD coatings can be both organic and inorganic, depending on the precursor choice and the experimental conditions used for the deposition. When the deposited film

Plasma-Enhanced Chemical Vapor Deposition, Fig. 1 Sketch of the activated growth model

is organic, the PECVD process is commonly referred to as “plasma polymerization,” and the precursor is termed monomer. However, plasma-deposited films pretty much differ from conventional polymers since their structure has no repeating unit. The layers deposited by PECVD are typically: (i) well adherent, (ii) pine-hole-free, (iii) amorphous and cross-linked, and (iv) conformal and 3D object compatible, (v) with tunable chemical composition and structure. This process allows for the deposition of films with thickness in the range 10–10,000 nm, with deposition rates normally of the order of tens of nm/s and in some cases hundreds of nm/s.

The growth mechanism of PECVD coatings, known as activated growth mechanism (AGM), has been deeply investigated (d’Agostino 1990; Milella et al. 2005; d’Agostino and Palumbo 2012) and is summarized in Fig. 1.

The monomer (*Mon*, step 1) is fragmented in the gas phase by electron impact (see ► [Cold Plasma](#) in this encyclopedia), with the formation of different radicals (*R*). Ion bombardment of the substrate and of the growing film influences the deposition rate since impinging ions transfer energy to the surface, eventually creating surface defect sites (active sites) with reduced activation energies for dissociative chemisorptions (*Substrate**, step 2). Radical species can then adsorb and react with the active sites, thus contributing to film growth (step 3). Bombardment of material surface by low-energy ions can lead to breakage of chemical bonds, surface diffusion,

and heating, which contribute to film densification and to enhanced film-substrate adhesion. Moreover, the energy transfer by impinging ions can favor the molecular dissociative chemisorption. High-energy ion bombardment can determine dramatic rearrangement of the structure of the growing film, such as sputtering of surface atoms, structural damage, and high internal stress. In this extremely reactive scenario, the film grows with a complex and cross-linked structure and with a not conventional chemical composition.

Instead of sticking directly to the surface of the growing polymer, radicals can also polymerize in the gas phase forming oligomers (*R_n*, step 4) or even powders (step 5) which can be afterwards included in the growing film (step 6). However, this second route generally leads to polymers less compact and with poor adhesion to the substrate.

Based on this mechanism it appears quite straightforward that the chemical composition and structure of PECVD films can be finely tuned by properly adjusting process parameters such as input power, pressure, feed composition, substrate temperature, and self-bias (see ► [Cold Plasma](#) in this encyclopedia).

In the field of membrane processing, PECVD can be used both to modify the surface of commercially available membranes and to prepare freestanding ones. These membranes mainly find applications in the field of gas and liquid separation, fuel cells, sensors, and biomaterials (Roualdes et al. 2010; Memoli et al. 2007; De Bartolo et al. 2005).

The gas and liquid permeability of membranes can be tuned with the aid of suitable PECVD coatings, through the control of the surface wettability or inducing specific chemical interactions between the permeant molecules and the film. Silicon oxide-like coatings have been widely exploited as barrier to control gas and vapors permeation (Coclite et al. 2010; Creatore et al. 2001; Julbe et al. 2008). Acid and base functionalized coatings can be deposited on conventional membranes to enhance their liquid or vapor separation performances (Weibel et al. 2007).

PECVD ion exchange membranes can mainly find application for the production of planar

proton exchange membrane fuel cells. Commonly, the membranes are prepared feeding the plasma with an acid precursor and a fluorocarbon monomer. The challenge in this kind of process is to retain in the deposited films the acid functionality, which can be easily cleaved in plasma. This is usually obtained by lowering the energy of the plasma by properly adjusting process parameters. Proton conductivities in the range of 10^{-3} –2 mS/cm have been reported; however, values as high as 180 mS/cm have been recently achieved (Brault et al. 2006; Thery et al. 2010).

Polyethersulfone (PES) membranes have been coated with plasma-polymerized acrylic acid for the subsequent immobilization of galactonic acid through a hydrophilic spacer arm molecule. This strategy allowed the setup of a bioreactor for biomimicking the cellular microenvironment accomplishing long-term maintenance and differentiation of human hepatocytes (Memoli et al. 2007; De Bartolo et al. 2005).

Plasma-Enhanced Chemical Vapor Deposition (Plasma Polymerization)

Stephanie Roualdes

IEM/UM II – CC 047, Place Eugene Bataillon, Montpellier, France

P

PECVD is the main effect caused by the interaction between a cold plasma (defined in the article entitled “Vapor Plasma Membrane Treatment”) and a material placed within it, in the case of condensable gases (organic, inorganic, or organometallic compounds) used as gaseous phases. PECVD is due to recombination of the reactive species adsorbed on the surface of the substrate and results in the formation, on the surface of the substrate, of a deposit made up of a three-dimensional matrix formed from fragments of the reagent gas combined in a random way.

The PECVD process is mainly used for the preparation of inorganic, hybrid, or polymer-like thin layers. In the field of membranes, most of the plasma deposits are prepared from organic precursors; in that case, one calls the deposition

process plasma polymerization preferentially to PECVD. Among the numerous PECVD parameters, the ones having a direct effect on the fragmentation of the precursor are logically the most influent. Three parameters have a particularly pronounced effect: the nature of the precursor represented by its molecular weight M , the power of the electric discharge W , and the precursor flow rate F . The energy-input level manifested by W/FM (given in units of J/kg, or energy per mass of monomer), introduced by Yasuda (1985), is the predominantly important factor determining the extent of fragmentation. Low W/FM values are related to operating conditions where the activated species have a far lower concentration than precursor molecules introduced into the plasma; in such a range of W/FM values, called precursor sufficient region, the number of activated species, and consequently the plasma film deposition rate, increases with W/FM . For medium W/FM values, corresponding to the competition region, the quantity of precursor molecules introduced into the plasma is exactly the quantity likely to be activated; in that case, the film deposition rate is invariable as a function of W/FM . For high values of W/FM , corresponding to the precursor deficient region, the material deposition rate decreases with W/FM because of the lack of precursor molecules likely to be activated.

Plasma deposits are disorganized thin films, with short and branched chains (randomly terminated with frequent cross-links) often not reminding the precursor(s) they come from. In terms of material properties, plasma deposits present a great number of advantages when compared to films synthesized, on the one hand, by other techniques of vacuum deposition, and, on the other hand, by liquid-route synthesis methods:

- Like all the vacuum deposition techniques, PECVD makes it possible to work out very thin films with thicknesses of a few nanometers to a few microns, which is impossible with liquid-route synthesis methods. The deposition rate can be high (several $\mu\text{m min}^{-1}$) (Storgaard-Larsen and Leistiko 1997) making the process ideal for industrial applications.

- One of the major interests of this technique is the possibility of depositing materials at ambient temperature on substrates sensitive to heat such as conventional organic polymers (which is not possible with conventional chemical vapor deposition (CVD): chemical plating in pyrolytic phase vapor). The polymeric supports constitute, with glasses, semiconductors, ceramics, and metal surfaces, the large variety of substrates on which the plasma deposits have a good adherence.
- The materials deposited by PECVD are generally dense, amorphous, strongly cross-linked, and present a low density of defects and holes compared with those obtained by the other vacuum deposition techniques such as evaporation or sputtering.
- The three-dimensional and highly cross-linked structure of the plasma deposits is at the origin of a number of very specific properties of these materials, properties that one does not find in their counterparts worked out by conventional ways: chemical inertia, good thermal stability, anticorrosive character, and barrier properties with respect to oxygen and water vapor in particular.
- PECVD makes it possible to adjust the chemical composition and the microstructure of deposited materials and thus to modify the physical and chemical properties of these materials by the simple variation of the parameters of the process, and this in a field much broader than the other deposition techniques. If, from a technological point of view, this requires a rigorous control of the parameters of the process, the complexity and variety of active species and reaction steps directly related to the plasma parameters offer a high degree of flexibility in prepared materials properties.

Plastron Effect

Wolfgang M. Sigmund¹ and Shu-Hau Hsu^{1,2}

¹Department of Materials Science and Engineering, University of Florida, Gainesville, FL, USA

²Department of Energy Engineering, Hanyang University, Seoul, Republic of Korea

Plastron, meaning shielding, was first used in 1910 by zoologist, F. Brocher, referring to a layer of gas adhering closely to the body surface between the hairs of underwater Coleoptera family (Brocher 1909). This air layer serves as an air supply for a variety of arthropods while performing living activities underwater. A well-known example is the water spider (*Argyroneta aquatica*), which spends its entire life living underwater (Fig. 1). The hairy structure of the water spider is thus necessary not only to lower the contact area with the water surface but to enable them to breathe when submerged. This activity is consequently termed *plastron respiration*. The gases, oxygen and carbon dioxide, are supplied and removed through the diffusion across the bubble surface from the ambient water. The air layer is maintained by an array of hair with their tips forming pillars lying roughly parallel to the body. The curvature pressure and the mechanical strength of hairs sustain the interface, while higher ambient hydraulic

Plastron Effect, Fig. 1 Air clinging to the hydrophobic hairs on the abdomen of a spider away from the diving bell (Seymour and Hetz 2011)

pressure may buckle the hairs causing the collapse of the plastron air. Earlier observations found that the collapsing point for most insects occurs in the pressure between 1 and 5 atm (Thorpe and Crisp 1947). With more sophisticated imaging equipment, calculations, however, estimated that the hairs should be stable at a pressure up to 40 atm (Hinton 1976).

Nowadays plastron is commonly used to describe the thin air layer trapped on submerged surfaces in Cassie-Baxter state. The air layer trapped by the superhydrophobic surface is thermodynamically unstable. Except for a few species that actively maintain the trapped air for breathing the air dissolves into the water. The lotus leaf loses its plastron air within an hour when immersed to the depth of half meter. The metastable underwater superhydrophobicity limits its potential applications, such as drag reduction or anticorrosion. The lifetime of plastron is controlled by the mass flux of air into water and is driven by partial gas pressure difference between the interface. The decay of plastron generally has two distinct phases. At the initial phase, air diffuses into water through the planar interface, and its mass flux shows exponential depth dependence. With further thinning to a critical thickness, the plastron forms into spherical cup-shaped air bubbles resulting in a rapid decay driven by the Laplace pressure (Poetes et al. 2010). The lifetime of plastron varies with its surface energy and topography, while detailed studies are still very limited to date.

Plate and Frame Membrane

► Plate and Frame Membrane Module

Plate and Frame Membrane Module

Joerg Balster

Application Technology, Evonik Fibres GmbH,
Schoerfling, Austria

Synonyms

Plate and frame membrane; Plate and frame module

The plate and frame module design provides a configuration which is closest to the flat membranes used in the laboratory (Mulder 1997).

The most important elements of the module construction are (Blackmer and Hedman 1979):

- Flat membrane
- Membrane supporting plate/spacer
- Feed distribution plate

In a plate-and-frame module configuration (Fig. 1), sets of two membranes are placed in a sandwich-like fashion with their feed sides facing each other. In each feed and permeate compartment, a suitable spacer is placed. A plate-and-frame stack is build up by the number of membrane sets needed for a given membrane

area equipped with sealing rings and two end plates. The packing density (membrane surface per module volume) of such modules is low and about 100–400 m²/m³ (Mulder 1997).

A schematic flow path in a plate-and-frame module is illustrated in Fig. 2. In order to reduce channeling (tendency to by-pass parts of the membrane along a short cut) and to establish a uniform flow distribution, baffles have been introduced (Mulder 1997).

The advantages of plate-and-frame modules are the following (Blackmer and Hedman 1979):

- Exchange ability of single membranes
- Low sensitivity to particulate blocking of the feed channels
- Usage of flat membranes without the usage of glue

The disadvantages are the following:

- Need of several sealings
- Pressure drop
- Low packing density

Plate-and-frame modules were the earliest version of membrane modules (Mulder 1997; Baker 2004) and are today still used in ultrafiltration and pervaporation processes. There is only one plate-and-frame configuration used in solution-diffusion membranes (Ohlrogge and Ebert 2006). This design may be relevant in the future for flat perovskite membranes (Etchegoyen et al. 2006; Melin and Rautenbach 2007; Kondo 1992).

Plate and Frame

Membrane Module,

Fig. 1 Drawing of a plate-and-frame module taken from Scholz et al. (2011)

Plate and Frame Membrane Module, Fig. 2 Schematic flow path in plate-and-frame-module taken from Scholz et al. (2011)

The plate-and-frame module is highly effective in pervaporation applications, but is much less popular than spiral wound and hollow fiber modules for gas separation applications due to the lower membrane area per unit volume that can be accommodated (Baker et al. 1991). The only commercial application for a plate-and-frame device in gas separation is the oxygen enrichment from air for small-scale medical applications (Lemanski and Lipscomb 2001; Bao and Lipscomb 2002) and for organic vapor recovery as commercialized by Borsig, with a special custom design envelope-type gas separation module (Scholz et al. 2011; Melin and Rautenbach 2007).

Platinum

Dmitri Bessarabov

Faculty of Engineering, DST HySA Infrastructure
Center of Competence, North-West University,
Potchefstroom, South Africa

Platinum

Platinum (Pt) is a chemical element with an atomic number of 78 and atomic mass of 195.09 (Platinum (Pt) 2012).

General Facts

Platinum has five naturally occurring stable isotopes and one naturally occurring radioactive isotope (Pt 190) that decays with a half-life of 6.5×10^{11} years. There are also a few known synthetic isotopes. Platinum is a silver-white metallic element. Platinum is a relatively rare and usually occurs in combination with other metals including iridium, osmium, or nickel. South Africa is the dominant supplier of Pt which accounts for approximately 80 % of the world production. The world's most important deposits occur in the North West Province of South Africa near Rustenburg and Brits.

Platinum is one of the six metallic elements forming the so-called PGM (platinum-group metals): ruthenium (Ru), rhodium (Rh), palladium (Pd), osmium (Os), iridium (Ir), and platinum (Pt). These elements are all transition metals clustering in the groups of 8, 9, and 10 and periods 5 and 6 in the periodic table.

Platinum has a melting point of 1,769 °C (Platinum (Pt) 2012) and density of 21.45 g/cm³ at 20 °C. It has a face-centered cubic crystal structure.

Use of Platinum

Platinum is used as a catalyst in the chemical industry (e.g., in sulfuric acid production,

petrochemistry) and in catalytic converters in the automotive industry. It is also used to make electrical components, corrosion-resistant chemical laboratory equipment, and jewelry. Platinum is also used in many medical applications (electrodes, dentistry, as a component for certain types of anticancer drugs, etc.). One of the potentially large applications for platinum and platinum-based alloys is its use in fuel cells as a catalyst.

Polarization in Membrane Operations

Maria Tomaszewska

Faculty of Chemical Technology and
Engineering, West Pomeranian University of
Technology, Szczecin, Poland

Polarization phenomena are inherent to all membrane separation processes. Since a membrane has the ability to transfer one component of a mixture more readily than others or to retain solutes completely, the rejected substances are gradually accumulated at the membrane surface, whereas a solvent permeates freely through the membrane. This leads to the formation of a boundary layer adjacent to the membrane, where the concentration of the retained solutes is higher than in a bulk solution (Fig. 1). This difference in the concentration of solutes is termed as **concentration polarization (CP)**. The CP phenomenon causes a serious problem in every membrane process because it reduces the driving force of the mass transfer and thus leads to a decrease in the permeate flux.

The extent of CP strongly depends on the type of membrane process, its driving force, and the feed

Polarization in Membrane Operations, Fig. 1 Concentration polarization. Concentration profile under steady-state conditions

composition. The **CP** effect is most severe when a permeate flux is high and the mass transfer coefficients (and diffusion coefficients) of the separated species are low (Table 1). Thus, the **CP** is especially severe in the case of pressure driven membrane techniques, such as microfiltration (MF) and ultrafiltration (UF), which are applied to separate the macromolecular solutes, small particles, colloids, and emulsions. The concentration of the accumulated molecules might be so high that a gel layer can be formed on a membrane, which induces an additional resistance to the mass transfer on the feed side.

In reverse osmosis (RO), an increase of salt concentration in the boundary layer can increase the osmotic pressure and reduce the driving force. The severity of **CP** in RO is lower than in MF or UF because the permeate flux is lower and the mass transfer coefficients of salts are high. However, an increase of salt concentration in the layer adjacent to the membrane results in their precipitation onto the membrane surface (scaling), which contributes to a decrease of permeate flux (Mulder 1991).

Scaling is also a serious problem in nanofiltration (NF). The **CP** in NF causes a reduction of a permeate flux mainly due to an increase

Polarization in Membrane Operations, Table 1 Effects of polarization concentration in various membrane operations (based on Mulder 1991)

Membrane operation	CP influence	Mass transfer coefficient/diffusion coefficient	Permeate flux
Reverse osmosis	Moderate	Large / $10^{-9} \text{ m}^2/\text{s}$	Small/moderate
Nanofiltration	Moderate	Large	Moderate
Ultrafiltration	Strong	Small/ 10^{-10} to $10^{-11} \text{ m}^2/\text{s}$	Large
Microfiltration	Strong	Small/ 10^{-10} to $10^{-11} \text{ m}^2/\text{s}$	Large
Gas separation	Very low	Large/ 10^{-4} to $10^{-5} \text{ m}^2/\text{s}$	Small
Pervaporation	Low	Large	Small
Electrodialysis	Strong		
Dialysis	Low	Large/ $10^{-9} \text{ m}^2/\text{s}$	Small
Membrane distillation ^a	Low	Large	Small/moderate

^aStrong influence of temperature polarization

of osmotic pressure of the retained salts. Moreover, similarly as in UF and MF, the accumulated organic molecules can form a gel layer (fouling or biofouling) (Schafer et al. 2005).

The concentration polarization also strongly limits the efficiency of electrodialysis (ED). The transport of charged molecules is the result of an electrical potential difference (driving force) through an ion-selective membrane. Cations are driven to cathode and anions to anode. For example, through a cation-selective membrane only cations can be transferred at the potential difference. However, the transfer across the membrane is faster than in boundary layers on both sides of the membrane. Thus, the concentration of cations will be lower at the membrane surface on the anode side and higher at the membrane surface on the cathode side (Fig. 2). Thus, **CP** appears on both sides of the membrane. Moreover, a diffusive flow occurs in the boundary layers (Mulder 1991).

The effect of **CP** on the membrane processes such as gas separation, pervaporation, and dialysis is low or very low (Table 1).

Polarization in Membrane

Operations,

Fig. 2 Concentration polarization in electrodialysis in the presence of cation-selective membrane

In the case when a hydrophobic membrane separates two solutions of different temperature as in membrane distillation (MD), the temperature and concentration polarization phenomena occur. In MD, only volatile components are transferred through a hydrophobic, porous membrane. Therefore, the energy required for water evaporation is supplied from hot feed solution on the liquid-membrane interface. As a result the local temperature in the boundary layer is gradually decreasing. On the cold side, the water vapor is condensed and energy (latent heat) is released, therefore, the temperature in the boundary layer increases. For this reason, the temperature of the liquid-membrane interface on both sides of the membrane is different from that in bulk solutions. This difference is referred to as **temperature polarization**. Additionally, an accumulation of solutes on the feed side leads to the concentration polarization.

The extent of **CP** can be reduced by increasing flow rate of the stream over a membrane, application of permeate pulsing, operation below a critical flux, or using an ultrasound system (Schafer et al. 2005).

Polyacetylene-Based Membrane Materials

Yuri Yampolskii

A.V. Topchiev Institute of Petrochemical Synthesis, Russian Academy of Sciences, Moscow, Russia

Many of disubstituted polyacetylenes are glassy polymers distinguished by extremely high gas permeability. The first polymer of this class poly(trimethylsilyl propyne) (PTMSP) was discovered by Masuda et al. (1983). All these polymers have very rigid main chains so the glass transition temperature is, as a rule, above the onset of thermal decomposition. PTMSP due to the bulky SiMe_3 side group has extremely large gas permeability coefficients (e.g., $P(\text{O}_2) = 6000$ Barrer): until very recently, it was considered as the most permeable polymer among all known. Recently, it was shown that other polyacetylenes reveal even higher gas permeability (Hu et al. 2008). Several structural analogs of PTMSP [poly(trimethylgermyl propyne) (PTMGP) and poly(methyl pentyne) (PMP)] also reveal high permeability. Many other disubstituted polyacetylenes have been prepared; they show a wide range of gas permeability (Nagai et al. 2001). Due to the trade-off between permeability and permselectivity, the most permeable polyacetylenes

are low selective materials. PTMSP is characterized by a large free volume as has been shown by positron annihilation lifetime spectroscopy (PALS). An unusual feature of PTMSP and other highly permeable polyacetylenes is a negative activation energy of permeation, that is, the permeability coefficients increase when temperature decreases. In contrast to conventional glassy polymers, PTMSP and its structural analogs reveal solubility-controlled selectivity in separation of hydrocarbons: the permeability coefficients are larger for higher gaseous hydrocarbons (e.g., n-butane) as compared to the permeability coefficient of methane (Pinnau and Toy 1996). This important feature makes them suitable membrane materials for separation of hydrocarbons of natural and associated petroleum gases. A disadvantage of highly permeable polyacetylenes is their tendency to aging, that is, a reduction of permeability in time. The rate of this process is especially high for PTMSP: for some samples, permeability decreases by a factor of 100 during 2 months of exploitation. This can be the main factor preventing practical applicability of highly permeable polyacetylenes in membranes. PTMSP and its structural analogs include double bonds in the main chains, so different cis-trans-configurations can be realized depending on the selection of a catalyst and polymerization conditions. The polymers with prevailing cis- or trans-configuration have somewhat different properties: solubility in various organic solvents, permeability coefficients, and tendency to aging. Since polyacetylenes are soluble in different organic solvents, composite membranes can be prepared from them. Thanks to the high permeability of these polymers, laboratory-scale membranes with very high permeance (say, 20–30 m³(STP)/m² h/bar) have been prepared and tested in different separation processes. It has been also reported that PTMSP can form good and permeable organophilic pervaporation and nanofiltration membranes (Volkov et al. 2009, 2013).

Polyacrylonitrile (PAN)

Alexey Volkov

A.V. Topchiev Institute of Petrochemical Synthesis, Russian Academy of Sciences (TIPS RAS), Moscow, Russian Federation

Polyacrylonitrile (PAN) is semicrystalline thermoplastic polymer (see Fig. 1 for structural formula of PAN), which is synthesized by radical polymerization in the presence of conventional initiators, for example, peroxides. There are six different technologies of production of monomer, acrylonitrile: (a) from ethylene via ethylene oxide and ethylene cyanohydrins, (b) oxidative ammonolysis of propylene or propane, (c) from acetylene and hydrocyanic acid, (d) from ethylene via acetaldehyde and hydroxynitrile, (e) from propylene and nitrogen oxide, and (f) from ethylene, hydrocyanic acid, and oxygen. PAN has a good resistance in a wide range of organic solvents:

Polyacrylonitrile (PAN),
Fig. 1 Structural formula
of polyacrylonitrile

Polyacrylonitrile (PAN),
Fig. 2 Radical mechanism
 of polyacrylonitrile
 cyclization

insoluble in hydrocarbons, chlorinated hydrocarbons, ketones, diethyl ether, and acetonitrile (Mark 2009). Major application of PAN is textile fibers.

When homopolymer PAN is heated above 180–200 °C, the autocatalytic reaction of cyclization takes place through a free radical mechanism (see Fig. 2). Further heat treatment leads to carbonization of initial material. PAN-based fibers are the main raw material for carbon fiber production. Polymer softening temperature is close to the one at which cyclization starts; therefore, PAN can be only processed to fibers by dry or wet spinning. Besides homopolymer, PAN copolymers can be used in order to improve carbon fiber quality. Carbon fibers have a number of advantages like low density, high stiffness, good chemical and temperature resistance. As a result carbon fibers are widely used in production of novel lightweight composite materials with high mechanical properties for different applications like aerospace industry, machinery and military applications, sports, and other applications (Gupta et al. 1991).

Different copolymers of acrylonitrile offer a large family of materials for different applications. Acrylonitrile-butadiene rubber with acrylonitrile content from 20 % to 50 % is known as nitrile rubber that has high oil and abrasion resistance. Copolymer of acrylonitrile with butadiene and styrene is a famous ABS plastic that is extensively used in different applications such as the automotive industry (e.g., bumpers), different plastic carcass, parts, and goods. Acrylonitrile and butadiene provide good hardness, while incorporated rubbery particles offer shock absorbance that makes this material less brittle. In addition, polar groups of acrylonitrile also provide interchain bonding to improve mechanical properties and good dimension stability. ABS has good chemical stability and low water adsorption and can be operated at low and high temperatures. ABS can be processed with standard methods (Rosato et al. 2000).

PAN has been widely used as a membrane material. Regarding transport properties, PAN belongs to the group of extra low permeable (barrier) polymers (e.g., $P(\text{CO}_2) \sim 10$ Barrer). Due to high chemical stability, PAN is used for fabrication of micro- and ultrafiltration membranes both for aqueous and nonaqueous applications. These flat membranes are fabricated on a nonwoven by a phase inversion process. It is worth to mention, that PAN ultrafiltration membranes are attractive for use as an efficient porous support for fabrication of thin film composite membranes for gas and vapor separations, pervaporation and organic solvent nanofiltration. Several companies have manufactured thin film composite membranes based on PAN porous supports over the years.

Polyacrylonitrile Membrane

George Dibrov

A.V. Topchiev Institute of Petrochemical Synthesis, Russian Academy of Sciences, Moscow, Russia

The majority of commercial methods of production of polyacrylonitrile (PAN) are based on free radical polymerization of acrylonitrile (Fig. 1).

Chemical and physical properties of PAN (Andrady 1999, Scharnagl and Buschatz 2001):

Polyacrylonitrile

Membrane, Fig. 1 The chemical structure of the polyacrylonitrile repeat unit

- Melting point: 317 °C
- Glass transition temperature: 87–125 °C
- Decomposition temperature: >250 °C
- Density: 1.17 g/cm³
- Solubility: DMF, DMSO, DMAc, NMP, dioxanone, chloroacetonitrile, dimethyl phosphite, dimethyl sulfone, ethylene carbonate, γ-butyrolactone, conc. sulfuric and nitric acid, and conc. salt solutions of LiBr or NaCNS in water
- Water uptake: 1–2.4 % (25 °C, 65 % rel. humidity)
- Good resistance against mineral acids and weak alkaline solutions, moderate against strong alkalines
- Permeability coefficient $P(\text{m}^3(\text{STP}) \cdot \text{m} \cdot (\text{s} \cdot \text{m}^2 \cdot \text{Pa})^{-1} \cdot 10^9)$ of unplasticized film at 25 °C: $P(\text{O}_2) = 0.00015$, $P(\text{CO}_2) = 0.00060$, $P(\text{H}_2\text{O}) = 230$

PAN membranes have attracted much attention due to a variety of excellent characteristics, which include thermal stability and tolerance to most solvents, atmosphere, bacteria, and photo irradiation. Therefore, their exploitation also covers many fields in micro- and ultrafiltration, pervaporation, nanofiltration, reverse osmosis like water treatment, enzyme immobilization, hemodialysis, concentration of whey or protein, concentration of oil/water mixtures, etc. PAN membranes demonstrate high stability against chemical cleaning agents and resistance to sodium hypochlorite, citric acid, weak alkaline solutions, hydrolysis, and oxidation. PAN is highly crystalline and relatively hydrophilic (calc. surface tension is 44 dynes/cm) and is usually copolymerized with more hydrophilic monomers to improve processability and to make it less brittle.

Preparation of PAN membranes is possible by phase inversion from its solutions. PAN membranes for ultra- and microfiltration are developed by GKSS (Scharnagl and Buschatz 2001).

Different membrane morphologies varying from large finger-like pores to homogeneous microporous structures can be obtained. The change from the finger-like pores to globular ones enhances the pressure stability of membranes, which is favorable to the use of membranes as supporting material for composite membranes.

The flux of the membranes can be adjusted between 100 up to nearly 2000 l · (m² · h · bar)⁻¹ with high rejection. By varying the formation parameters, a wide spectrum of membranes with different average pore diameters ($d_{50} = 2\text{--}70$ nm) can be produced. PAN membranes are used in a plate-and-frame module developed in the GKSS research center and now sold by Amafiliter. This module is applicable to nano-, ultra-, and microfiltration and also appropriate for high values of suspended solids. For water reuse, the PAN membranes are also used in Rochem FM-modules.

Microza[®] hollow fiber ultrafiltration modules produced by Pall Corporation feature unique double-skinned polyacrylonitrile (PAN) membranes with dense internal layer. The modules are used in a range of pharmaceutical applications especially in purification and processing of aqueous enzymes and protein solutions, raw water pretreatment to pharmaceutical water purification plant. UF membranes from PAN and its copolymers are also produced by Millipore and Applied Membranes Inc.

PAN can be chemically cross-linked with and without the change in the porous structure of the membrane (Nunes and Peinemann 2001). The surface of PAN membranes can be modified by plasma or conversion of nitrile groups (Ulbricht 2006).

Polyamide (PA)

W. J. Lau

Advanced Membrane Technology Research Centre (AMTEC), Universiti Teknologi Malaysia, Skudai, Johor, Malaysia

Polyamide (PA) is a polymer where the monomer units are connected together by amide group ($-C(=O)-NH-$). It can be easily synthesized by interfacial polymerization (IP) between polyfunctional amine monomer and polyacyl chloride monomer at the interface between two immiscible solvents with hydrochloride acid (HCl) created as by-product. The concept of IP was first introduced by Morgan in the 1960s (Morgan 1965). The contribution of IP technique to the development of membrane science and technology is so significant, making it almost equivalent to the historical announcement of Loeb-Sourirajan asymmetric membrane prepared from phase inversion technique. By employing this IP technique, an ultrathin, selective PA layer (with thickness between 100 and 500 nm) is able to form over the surface of microporous support membrane, producing a thin-film composite (TFC) membrane with a very good combination of water flux and solute rejection.

Conventionally, interfacially polymerized PA layer is established by immersing support membrane in an aqueous solution containing amine monomer (with concentration mostly between 0.1 % and 1 % w/v), followed by organic solution of acyl chloride monomer (mostly between 0.05 and 0.2 % w/v) which is immiscible with the first aqueous solution (Lau and Ismail 2011). The membrane is then subject to heat treatment process at temperature in the range of 70–90 °C to densify the polymerization properties of PA layer.

The sequence of immersion process however can be reversed if the support membrane is relatively hydrophobic in nature (Wu et al. 2010). It is mainly because hydrophobic substrate can be well contacted with organic solution of acyl chloride monomer, leading to higher degree of cross-linked PA layer. It has also been reported that the unreacted acid chloride groups on the surface of PA layer could be further reacted by placing the membrane in aqueous solution of amine monomer for second time after the conventional IP approach (Zou et al. 2010). The modified approach is reported to yield membrane surface with larger amount of amino groups ($-NH_2$), causing the membrane to have better antifouling properties than that of membrane prepared from conventional IP approach.

Characteristics of PA are varied depending on the type of amine and acyl chloride monomers selected during IP process (Lau et al. 2012). Figure 1 shows the most frequently used aromatic diamine monomer and bi-/tri-acyl chloride monomers in preparing cross-linked aromatic PA layer. The degree of PA cross-linking depends on not only the organic structure of the monomers used but also factors such as concentration of active reactant in aqueous/organic solution, type of hydrocarbon solvent, reaction time, presence of additive/surface, etc. Figure 2 shows the possible PA structures formed from the reaction of *m*-phenylenediamine (MPD) with trimesoyl chloride (TMC). It is generally agreed that the poly (MPD-TMC) chain is to contain both the cross-linked structure and non-cross-linked (i.e., linear) structure. The carboxylic acid functional group ($-COOH$) arises due to the partial hydrolysis of the acyl chloride unit of TMC during IP. In order to grasp the cross-linking reaction rate of the PA formed, characterizations using Fourier transform infrared (FTIR) spectrometer and X-ray photoelectron spectra (XPS) are generally performed.

However, it must be pointed out that PA is very susceptible to free chlorine attack, causing it to lose its integrity. By exposing PA to chlorine solution, several chemical changes in PA have been proposed. These include (a) chlorination of N–H group of diamine to form N–Cl group, (b) Orton rearrangement – initial chlorination of

Polyamide (PA), Fig. 1 Organic structures of (a) aromatic diamine monomer and (b) bi-/tri-acyl chloride monomer used in synthesizing polyamide

Polyamide (PA), Fig. 2 Possible chemical structures of polyamide prepared from MPD and TMC, (a) linear structure with a pendant COOH group from the hydrolysis

of COCl , (b) cross-linked with a pendant NH_2 group and (c) totally cross-linked polymer chain

the N–H group followed by rearrangement of chlorine to aromatic ring of diamine unit, and (c) direct chlorination of aromatic ring of the diamine unit (Buch et al. 2008). Although PA in nature has low chlorine resistance, the recent research activities in utilizing new types of monomers such as melamine (Han 2013), m-phenylenediamine-4-methyl (MMPD) (Yu et al. 2009), N,N'-dimethyl-m-phenylenediamine (N,N'-DMMPD) (Shintani et al. 2009), and 1,3-cyclohexanebis(methylamine) (CHMA) (Buch et al. 2008) have improved the stability of PA against chlorine stability to a certain extent depending on the

concentration of chlorine solution and exposure period.

Polyamide Membrane

W. J. Lau

Advanced Membrane Technology Research Centre (AMTEC), Universiti Teknologi Malaysia, Skudai, Johor, Malaysia

Thin film composite (TFC) polyamide (PA) nanofiltration (NF) and reverse osmosis

(RO) membranes have been widely applied in many industrial applications such as water purification, wastewater treatment, desalination, food processing, and bio-separation, owing to its right combination of water flux and rejection compared to the typical asymmetric membranes.

Typical TFC PA membrane consists of three different layers made of different materials. Figure 1 illustrates the cross-sectional view of a PA membrane with top thin active layer made of cross-linked PA synthesized on a microporous substrate supported by a backing layer. The top active layer is prepared via interfacial polymerization technique, while the microporous substrate is commonly fabricated through a dry-wet phase inversion technique. The combined fabrication techniques offer distinct advantages as either active layer or substrate can be independently optimized to achieve desirable membrane properties such as high flux/high rejection and greater mechanical strength and compression resistance (Lau and Ismail 2009).

Figure 2 shows the two commonly used active monomers in preparing thin active layer of PA membrane together with the polymer used in microporous substrate preparation. In order to establish a very thin PA active layer on top of a substrate membrane, the substrate is first immersed into an aqueous solution consisting of amine monomer followed by immersion in second hydrocarbon solution of acyl chloride monomer. The membrane is then subject to heat treatment process to densify the polymerization properties of PA layer and/or enhance adhesion of PA thin layer to surface of substrate membrane. The

Polyamide Membrane, Fig. 1 Schematic diagram of typical thin film PA membrane made of different three different layers

Polyamide Membrane, Fig. 2 Organic structure of polymer used in thin film PA membrane preparation, (a) top active PA layer synthesized by interfacial polymerization between *m*-phenylenediamine (MPD) in water and trimesoyl chloride (TMC) in hydrocarbon solution and (b) polysulfone (PSf) for microporous substrate preparation

Polyamide Membrane, Fig. 3 The change in the characteristics of PA layer as a result of Orton rearrangement caused by the interaction between an aromatic amide and active chlorine (Kawaguchi and Tamura 1984)

chemical and physical characteristics of the interfacially formed PA film are strongly dependent on a number of important variables. These include type of monomer, concentration of monomer, partition coefficient of monomer, type of hydrocarbon solvent, overall kinetics and diffusion rates of monomer, reaction time, presence of additive/surfactant, posttreatment of the resulting interfacial PA film, etc. (Petersen 1993; Lau et al. 2012). All these variables listed should be taken into consideration during PA membrane fabrication as they play important role in PA layer formation which governs the performance

properties of membranes with respect to permeability/selectivity, fouling resistance, and chlorine tolerance.

A key limitation to typical PA membrane is its poor resistance to continual exposure to chlorine – one of the common disinfectants used in water and wastewater treatment, even at few ppb of chlorine. The changes in chemical and physical nature of PA layer upon chlorine exposure are identified as the main reason causing the membrane performance degradation, shortening membrane lifespan (Misdan et al. 2012). It is reported that the presence chlorine in water is

Polyamide Membrane, Fig. 4 Organic structure of advanced active monomer in preparing chlorine-resistant PA membrane, (a) m-phenylenediamine-4-methyl (MMPD) (Yu et al. 2009), (b) 1,2,4,5-benzene tetracarbonyl chloride (BTC) (Hong et al. 2013), (c) melamine (Han 2013), and (d) *N,N'*-dimethyl-m-phenylenediamine (*N,N'*-DMMPD) (Shintani et al. 2007, 2009)

able to attack the PA structure by forming N-chlorinated amide in the initial step of chlorination process. The process is followed by an irreversible reaction, i.e., ring chlorination through intramolecular rearrangement of chlorine atom into aromatic ring of the diamine moiety via Orton rearrangement as illustrated in Fig. 3 (Kawaguchi and Tamura 1984). Usually, the degree of membrane degradation following the chlorine attack is strongly dependent on the chlorine concentration and the membrane exposure time in feed water which can be expressed as ppm-h. To overcome the limitation of PA membrane without sacrificing its excellent water permeability and selectivity, many attempts have been made over the past several years to develop chlorine-resistant membrane with the use of novel advanced monomers in which some of the research works published have shown promising results in improving membrane stability against chlorine exposure. Figure 4 shows the potential monomers that have been used in improving membrane chlorine resistance. The PA membrane prepared from these monomers in general showed greater or much higher chlorine resistance than the commercial PA membranes.

Polydimethylsiloxane (PDMS)

Alexey Volkov

A.V. Topchiev Institute of Petrochemical Synthesis Russian Academy of Sciences (TIPS RAS), Moscow, Russia

Polydimethylsiloxane (PDMS) is the most known organosilicon rubbery polymer and its glass transition temperature is about -150°C . PDMS, often referred to as “silicone rubber,” can be polymerized from different monomers by hydrolysis

$$\left[\begin{array}{c} \text{CH}_3 \\ | \\ -\text{Si}-\text{O}- \\ | \\ \text{CH}_3 \end{array} \right]_n$$

PDMS is used as adhesive material, particularly, pressure-sensitive materials. Due to good dielectric properties, PDMS is also used for dielectric encapsulation. PDMS is extensively utilized as a polymer matrix for further incorporation of different kinds of

PDMS exhibits the highest values of gas and vapor permeabilities among rubbery polymers. By this reason, it has been extensively studied as a membrane material for different applications, namely, gas and vapor separation (Freeman et al. 2006), organophilic pervaporation (e.g., bioalcohols recovery from fermentation broth) (Vane 2005), and organic solvent nanofiltration (Volkov et al. 2008). PDMS can be used to fabricate hollow fiber, tubular, unsupported sheet, or thin-layer supported sheet membranes. Several companies have manufactured thin PDMS supported membranes over the years.

Poly(dimethylsiloxane) [PDMS] is often referred to as the “silicone rubber.” In the PDMS structure

Polydimethylsiloxane Membrane, Fig. 1 The chemical structure of the poly(dimethylsiloxane)-repeating unit

Polydimethylsiloxane Membrane, Table 1 Permeability and selectivity data of different gasses and vapors in PDMS RTV 615 (General Electric), measured at 40 °C (Blume et al. 1991). 1 barrer = $1 \cdot 10^{-10} \text{ cm}^3(\text{STP}) \cdot \text{cm} \cdot (\text{cm} \cdot \text{sec} \cdot \text{cmHg})^{-1}$

Gas/vapor	Permeability, barrer	Ideal selectivity over N ₂
N ₂	280	—
O ₂	600	~2
CO ₂	3200	~12
H ₂ O	23,000	~80
C ₂ H ₅ OH	45,000	~160
Chloroform	283,000	~1000
Toluene	1,460,000	~5200

(Fig. 1), the (–Si–O–Si–) backbone is highly flexible compared to many other rubbery polymers, and interactions between the individual PDMS segments are relatively weak. Consequently, PDMS has one of the lowest glass-transition temperatures for polymers of –127 °C, which allows long-range segmental motions even at very low temperatures resulting in one of the lowest diffusivity selectivity for permeation.

PDMS can be used to fabricate hollow fiber; tubular, unsupported sheet; or thin layer-supported sheet membranes. PDMS also has very interesting properties as a membrane material, and these properties have been utilized for a long time in membrane technology practice. Silicone rubber is extremely permeable and has adequate vapor/inert gas selectivity for the most applications (Table 1). The values may vary for different types of prepolymer solution and cross-linking agent and the chosen ratio. Mixed gas permeabilities deviate from the pure gas permeabilities.

The differences in permeability of vapor molecules through PDMS are mostly governed by their solubility coefficients rather than their

diffusivity coefficients. Penetrant solubility in rubbery polymers frequently increases with pressure, particularly for organic vapor penetrants, leading to a corresponding increase in permeability. As a result of the interaction between these factors, the permeability coefficients of low-sorbing penetrants, such as H₂, which do not plasticize PDMS and have essentially pressure-independent solubility coefficients, decrease very slightly with increasing penetrant pressure. In contrast, the permeability coefficients of more soluble penetrants, such as C₃H₈, which induce significant plasticization and have solubility coefficients that also increase with pressure, increase with increasing pressure (Merkel et al. 2000).

PDMS is the current benchmark hydrophobic pervaporation membrane material used, for instance, in the removal of VOC components from aqueous streams. Several companies have manufactured thin PDMS-supported membranes over the years. At present, Membrane Technology and Research (MTR), Inc., of Menlo Park, CA, is the leading supplier, manufacturing spiral wound modules out of their supported silicone rubber membranes. Ethanol–water separation factor for PDMS membranes ranges from 4.4 to 10. Butanol–water separation factors for PDMS also cover a fairly broad range, from 40 to 60. PDMS will, at least for the near term, continue to be the dominant organic membrane material for the recovery of alcohols from water (Vane 2005).

PDMS coatings are applied on a large scale in solvent-resistant nanofiltration to separate low molecular weight components from solvents such as toluene. PDMS coatings are applied to plug defects in gas separation membranes. In all these examples, the high permeability of PDMS is exploited (de Jong et al. 2006).

Polyelectrolyte Membrane for OSN

Pejman Ahmadiannamini

Biomedical Engineering, University of Arkansas, Fayetteville, AR, USA

Polymeric charged nanofiltration (NF) membranes have received a growing interest for water desalination and purification. Selective properties of charged NF membranes can be based upon not only the “sieving effect” but also the “charge effect.” Thus, the surface charge density of the membranes and the structure of the functional groups in the selective layer are imperative factors to determine their performance.

The range of NF applications has recently been broadened to organic feeds in organic solvent nanofiltration (OSN), also known as solvent-resistant NF (SRNF). A more widespread use of OSN requires solvent-resistant membranes that preserve their separation characteristics under more aggressive conditions of aprotic or strongly swelling solvents and elevated temperatures (Vandezande et al. 2008).

Alternate layer-by-layer (LbL) deposition of polyelectrolytes (PEs) of opposite charges has emerged as a versatile and inexpensive method to prepare thin films in the nanometer range for different applications (Decher 1997). A number of parameters, such as PE type and molecular weight of the PE, ionic strength, and pH of the

PE solutions, can influence the structure of the PE multilayer (PEM) films deposited by the LbL method. Films prepared via this method are in particular attractive materials with controlled thickness and surface properties for OSN (Li et al. 2008; Ahmadiannamini et al. 2012a).

PEs can be regarded as strong or weak depending upon degree of ionization of charged species. It is identified as strong when the dissolved PE dissociates completely and as weak when it is partially ionized. Charge density of weak PEMs can be affected by more factors than with strong ones, such as salt concentration and pH. This offers more possibilities to control membrane morphology and performance. A higher charge density is expected to lead to thinner deposited layers. Indeed, the self-repulsion of the chains is increased, and such polymer chains thus possess a larger cross-sectional area in solution, thus covering a larger surface upon adsorption on the substrate (Schönhoff 2003).

Both weak and strong PEs have been used for the buildup of PEM membranes. Comparison of their NF and OSN performances reveals that contrary to the applications in aqueous NF, PEM membranes constructed from weak PEs have retentions comparable to those of membranes prepared from strong PEs (Tables 1 and 2) (Ahmadiannamini et al. 2012a).

Another important parameter which can influence properties of PEMs is the charge density (ionic cross-linking) of the multilayer which is defined as the number of ion pairs per number of carbon atoms in the repeat unit (Krasemann and Tieke 2000). PEMs with higher ionic cross-link densities shrink less drastically in organic solvents and show higher permeances.

A very complex interplay of different contributions caused by mutual PE-solvent-solute-membrane interactions has to be taken into

Polyelectrolyte Membrane for OSN, Table 1 NF performance of PEM membranes in aqueous applications

account. PEM membranes are stable in a wide variety of organic solvents, and their performance is better than that of the different commercial membranes (Table 3), as very high retentions are combined with superior fluxes (Ahmadiannamini et al. 2012b).

Polyether Block Amide (PEBAX)

Anja Car

Department of Chemistry, University of Basel, Basel, Switzerland

Polyether block amide is a multiblock copolymer with two types of segments, rigid polyamide (PA) and flexible polyether known under the trade name Pebax® (<http://www.pebax.com/sites/pebax/en/home.page>). It is obtained by

Polyether Block Amide (PEBAX), Fig. 1 Chemical structure of Pebax[®]

polycondensation reaction (Fakirov 2005) of a carboxylic acid polyamide (PA6, P11, P12) with an alcohol-terminated polyether either polytetramethylene glycol (PTMG) or polyethylene glycol (PEG) with general chemical structure (Fig. 1):

Pebax[®] consists of a linear chain of polyamide and polyether segment (block) in an orderly pattern and belongs to the group of thermoplastic elastomers (Holden et al. 1996). The combination of the rigid PA segment and the flexible polyether segment yields a block copolymer that exhibits a microphase-separated morphology (Bates 1991) due to the polarity differences between them: a crystalline PA and an amorphous polyether phase. The crystalline phase allows the copolymer to behave as a thermoplastic and the amorphous phase imparts elastomer characteristics. The PA block melts in the range 130–200 °C (Rulkens et al. 2012); the exact value depends on average molecular weight and content of the PA in the copolymer. Polyether block crystallizes at low temperatures, the value of which lies between –30 °C and 20 °C mostly depending on its molecular weight of the sequences (Bailey and Koleske 1976). The glass-transition temperature (*T_g*) is about –50 °C due to the flexible segment (Patel and Spontak 2004). Through a proper combination of the polyamide and the polyether blocks, a wide range of Pebax[®] grades with a variety of end-use characteristics can be designed (Pebax[®] Technical Data Sheets). In general, these polymers possess a broad range of flexibility without the use of additives while maintaining high strength and toughness. Because of the thermoplastic qualities, it can be easily processed, extruded, and shaped at elevated temperatures, and upon cooling, its elasticity will allow it to return to its original length or shape after being stretched, compressed, or deformed. Depending on the nature and the relative content of both

segments, certain grades of Pebax[®] copolymers have great film-forming ability; thus, they attracted greater attention as a promising membrane material (Blume et al. 1990). The material offers strong resistance to a range of chemicals, and it is not affected by exposure to saline or sulfuric acid (Carson et al. 2010). It can be sterilized by a variety of methods including gamma radiation and steam autoclave. Pebax[®] is considered as a high performer among its thermoplastic elastomer peers because it is lightweight and because it offers a wider range of flexibility and hardness, a higher energy return, a greater resistance to fatigue, and better dimensional stability under physical and thermal stress (McKeen et al. 2010).

Polyetherimide Membrane

S. M. Javaid Zaidi^{1,2} and Kripal S. Lakhi¹

¹Australian Institute for Bioengineering and Nanotechnology, The University of Queensland, Brisbane, QLD, Australia

²King Fahd University of Petroleum and Minerals, Dhahran, Saudi Arabia

Polyetherimide (PEI hereafter) is one of the derivatives of a broad class of materials known as polyimides. PEIs are thermoplastics having excellent chemical and mechanical stability with high glass transition temperature and find its usage in numerous applications. Polyimides are polymers containing imide group sandwiched between two aromatic rings as shown in the Fig. 1. In order words, in polyimides, a nitrogen atom is shared between two carbonyl functions (Seifert et al. 2002). PEIs can be prepared by two different schemes, one of which involves nucleophilic substitution reaction and the other scheme consists of condensation reaction between diamines and dianhydrides. The latter method is more commonly employed than the former (Sedigh et al. 1999).

Further, PEI, a derivative of polyimide, is obtained by inserting ether groups within the polyimide backbone. The presences of ethereal linkages provide good processability, while aromatic groups attribute high performance characteristics. In recent years, there has been a number of reports projecting PEI membranes as a suitable material for biotechnological and biomedical applications since the requirements for biomedical applications are rather too stringent to be satisfied by other polymeric membranes. For

instance, development of biohybrid organ such as the liver support system would require a membrane material to have biocompatibility with blood and tissue cells at the same time (Seifert et al. 2002). A major advantage of the inherent structure of PEI membranes is the presence of polarized carbonyl groups that can be easily functionalized using different ligands and groups as per the requirement. Surface functionalization of PEI could produce membranes that are compatible with blood on one side and with tissue cells on the other side. Recent reports have indicated that PEI possesses excellent mechanical strength and thermal stability and high glass transition temperature. These properties together with its ability to allow attachment and growth of cells and almost insignificant cytotoxicity to cells make it the most promising biomaterial for biotechnological and biomedical applications (Seifert et al. 2002). Further, the PEI polymers can be used for preparing highly asymmetric membranes for selective separation of pair of gases, such as binary mixtures of H₂ and CH₄, CO₂ and CH₄, and CO₂ and N₂ and ternary of CO₂/H₂/CH₄ etc. (Shen et al. 2004; Park and Lee 1995; Ahmad et al. 2010; Sedigh et al. 1999). These are difficult separations, which can only be achieved by these membrane processes, and are widely used in industry these days. Moreover, PEI membranes can also be used in ultrafiltration and microfiltration and in vapor permeation of water/1-propanol, but its use is limited by the low hydrophilic nature of PEI membranes (Shen et al. 2004; Li et al. 2008).

The excellent properties of PEIs have been utilized by blending it with other well-known polymers thereby widening the scope of its utilization and application. Reports have indicated that PEI could be used to reduce the swelling as

Polyetherimide Membrane, Fig. 1 General structure of a polyetherimide (PEI)

well as improve mechanical stability of sulfonated (ether ether) ketone (SPEEK) membranes when blended in small proportion with SPEEKs (Bowen et al. 2004). Carbon molecular sieve (CMS) membranes have been extensively used for removal of CO₂ from natural gas as they have pores of relatively uniform dimension which aids in discrimination of molecules of very similar dimensions (Sedigh et al. 1999). CMS membranes are prepared by carbonization of PEI precursors and find extensive application in solving crucial environmental problems such as removal of sulfur from gasoline by pervaporation process (Changewi et al. 2009). Applications of PEIs abound in the biomedical domain as evident from a recent report where PEIs functionalized with groups such as hydroxyl (-OH), amines (-NH_x), carboxylic acids (-COOH), and sulfate (-SO₄) have been reported to be successful in preventing thrombosis, a major complication that results from a foreign surface that comes in contact with blood. Of these, PEIs functionalized with carboxylic acid have been reported to possess the best blood-contacting properties (Tzoneva et al. 2008).

Polyethersulfone (PES)

Fen Ran

School of Material Science and Engineering,
State Key Laboratory of Advanced Processing
and Recycling of Non-ferrous Metals, Lanzhou
University of Technology, Lanzhou, China

Polyethersulfone (also called 4,4'-sulfonyldiphenol polymer, poly(oxy-1,4-phenylenesulfonyl-1,4-phenylene), or poly(oxy-p-phenylsulfonyl-p-phenylene), abbreviated as PES) is an amorphous, transparent, and pale amber high-performance thermoplastic consisting of repeating phenyl groups linked by thermally stable ether and sulfonic (-SO₂-) groups. Its structure, as shown in Fig. 1, is similar to that of polyetheretherketone, but a sulfonic group replaces the right-hand -O-phenyl-CO- section. PES is the most temperature-resistant transparent commercially available thermoplastic. It has relatively high water absorption, and, in common with many other plastics, drying is essential before, e.g., thermoforming. It has poor fatigue characteristics and is prone to environmental stress cracking but has good long-term thermal aging resistance and reasonable radiation resistance. It belongs to high Tg polymers. Generally, PES possesses high

Polyethersulfone (PES), Fig. 1 Chemical structure of polyethersulfone

mechanical intensities, thermal stabilities, and chemical resistances. In addition, it has low creep properties, flame retardancies, excellent insulation properties, high dielectric strengths, and the lowest smoke-emission ratings among plastics.

PES was first manufactured by ICI Company (UK) in 1972. Nowadays, the main trade names and manufacturers of PES are Victrex TM (ICI company, UK), Ultrason TM (BASF company, Germany), and AstyleTM (3M company, USA). Both neat and reinforced grades are available in granule form for extrusion and molding. Unreinforced grades are used in high-temperature electrical applications, bakery-oven windows, and medical components. Reinforced grades are used for radomes, structural aircraft and aerospace components, and corrosion-resisting applications in packaging and chemical-plant hardware. PES is also widely used in aviation, microelectronics, automobile, membrane separation, etc. In membrane separation fields, PES has been prepared to ultrafiltration, reverse osmosis, and nanofiltration membranes. Filter cartridges made from PES membranes offer extremely high flow rates at very low differential pressures when compared with nylon or polypropylene media. Additionally filter cartridges made from PES can be sterilized within line steam or in the autoclave without loss of integrity up to 50 times.

For functional application, PES is often used as a copolymer. Sulfonated polyethersulfones (SPES) are synthesized as a promising material candidate among many other aromatic hydrocarbon-based polymers for highly durable, proton exchange membrane in proton exchange membrane fuel cell applications (Hickner et al. 2004). The biggest challenge for SPES application in fuel cells is improving its chemical durability (Borup et al. 2007). Under oxidative environment, SPES can undergo sulfonic group detachment and main chain scission. However the latter is more dominant; midpoint scission and unzip mechanism have been proposed as the degradation mechanisms depending on the strength of the polymer backbone (Lawrence and Yamaguchi 2008).

PES is also widely used as biomaterials due to its thermal stability, mechanical strength, and chemical inertness. Heparin-like poly(ethersulfone) (HLPES), with ionic groups of

$-\text{SO}_3\text{Na}$ and $-\text{COONa}$ on its macromolecule, is also synthesized by a combination of polycondensation and post-carboxylation methods. HLPES show good blood compatibility and good cytocompatibility (Wang et al. 2013).

PES allows easy manufacturing of membranes, with reproducible properties and controllable size of pores down to 40 nm. Such membranes can be used in applications like hemodialysis, wastewater recovery, food and beverage processing, and gas separation (Zhao et al. 2013).

Polyethersulfone Membrane

Fen Ran

School of Material Science and Engineering, State Key Laboratory of Advanced Processing and Recycling of Non-ferrous Metals, Lanzhou University of Technology, Lanzhou, China

Polyethersulfone (PES) membrane is one of the most important polymeric membrane and is widely used in separation fields. PES membranes show outstanding oxidative, thermal, and

hydrolytic stability as well as good mechanical property. The membranes always show asymmetric structure and are prepared by a phase inversion method. The membrane structure is influenced by the composition such as concentration, solvent and additives, and temperature of PES solution, the non-solvent or the mixture of non-solvents, and the coagulation bath or the environment, and so on (Barth et al. 2000).

Polyethersulfone is considered one of the most important polymeric materials for use in membrane applications. With transparent and amorphous properties and a high T_g (225 °C), this polymer has high mechanical, thermal, and chemical resistances, making it ideal for use in preparing asymmetric membranes with different pore sizes and surfaces. Compared with multiple membrane materials, PES has low hydrophilic properties. Significant research has been reported on efforts to change the surface properties of the PES hydrophobic membranes (Van der Bruggen 2009). PES membrane is stable in water and is an inert membrane and acts as only as a barrier in separation process, thus not fitted to the advanced separation fields, such as intelligent separation.

There are two main membrane shapes, flat-sheet and hollow fiber membranes. Due to the different shapes, the preparation process is different. For flat-sheet PES membrane, phase inversion technique is usually used. The polymer solution was cast on a support material (glass, polymer, metal, nonwovens), and after immersing into non-solvent

(usually water), flat-sheet PES membrane will be obtained. However, for hollow fiber PES membranes, a professional apparatus containing at least a spinneret and a take-up unit is needed. PES hollow fibers are prepared by a dry-wet-spinning technique (wet-spinning technique is seldom used) based on phase inversion (Khayet and Garca-Payo 2009). The typical field emission scanning electron micrographs of flat-sheet and hollow fiber PES membrane is shown in Fig. 1.

PES membranes are widely used in water treatment, protein and enzyme filtration sterilization, biological fluid filtration sterilization, tissue culture media sterilization, and pharmaceutical sterilizing filtration. PES membrane filters are composed of PES and manufactured within a tight specification range to ensure a uniform pore structure for low binding applications where reliable fast flow rates and high throughputs are required. PES filters are hydrophilic and can withstand high temperatures 135 °C (275 °F) without membrane degradation as required for autoclaving applications. It is also widely employed in biomedical fields such as artificial organs and medical devices used for blood purification (hemodialysis, hemodiafiltration, hemofiltration, plasmapheresis and plasma collection) (Ran et al. 2014).

Though PES membranes have been widely used, they have disadvantages. The main disadvantage of the membrane is related to its relatively hydrophobic character. So the current trend is to develop new membrane materials and structures specifically in

P

Polyethersulfone Membrane, Fig. 1 Field emission scanning electron micrographs of flat-sheet (*left*) and hollow fibers (*right*) PES membrane

view of reducing fouling effects, biocompatibility, and other functions. For the modification of PES membranes, there are three approaches: bulk modification of PES material, and then to prepare modified membrane; surface modification of prepared PES membrane; and blending, which can also be regarded as a surface modification. The modification procedures allow finding a compromise between hydrophobicity and hydrophilicity, localize the hydrophilic material specifically in the membrane pores, where they have a positive effect on flux and fouling reduction, and endow functions of membranes such as good blood compatibility and stimuli-responsivity (Zhao et al. 2013).

²King Fahd University of Petroleum and Minerals, Dhahran, Saudi Arabia

Polyethylene (PE) is a polymer obtained by polymerization of ethylene. Polyethylene is produced

in three different grades depending on the polymerization processes: low-density polyethylene (LDPE), linear low-density polyethylene (LLDPE), and high-density polyethylene (HDPE). Polymerization of ethylene is carried out in the presence of Ziegler-Natta catalyst, and the reaction mechanism involves three steps, namely, initiation, propagation, and termination. The properties of the polymer depend on the operating temperature, pressure, and the reaction time. Temperature control is critical in the polymerization process due to the exothermic nature of the reaction. PE-based membranes are highly versatile and have been investigated for quite some time for numerous applications such as fuel cell research, biotechnology, and biomedical applications including applications involving environment monitoring (Amada et al. 1994; Matsuyama et al. 2003; Sherazi et al. 2013).

Recent reports have shown that surface-functionalized porous PE membranes have large protein adsorption capacity and are preferred over inorganic materials for binding large quantity of biomolecules. In particular chemically modified sintered porous PE-based membranes have been found to have a number of advantages. These membranes are cost-effective; the textural parameters such as pore size, pore volume, pore size distribution, and surface area can be easily tuned and consequently find applications in separation and purification of proteins including peptide synthesis (Greene et al. 2005). Another phenomenal application of nanoporous PE membrane is in the development of glucose sensors that would detect, quantify, separate, and control transport of glucose. Such devices are absolutely essential for people suffering from diabetes (Uehara et al. 2011). LLDPE membranes are used in packaging industry because of their excellent mechanical and gas transport properties. It has been reported that the gas permeability (P) through these membranes increases according to the following order $P(\text{CO}_2) > P(\text{He}) > P(\text{O}_2) > P(\text{N}_2)$ in the temperature range 298 to 348K, and the diffusion coefficient for these gases follows the following order $D(\text{He}) > D(\text{O}_2) \geq D(\text{CO}_2) \geq D(\text{N}_2)$. The disagreement in the trend for permeability and diffusion coefficients highlights that mass transport through the

membrane is dependent on the solution process (Villaluenga and Seoane 2001).

High cost of the proton exchange membranes coupled with the use of precious metals (such as platinum and ruthenium) as catalyst has largely affected the commercialization of polymer electrolyte membrane fuel cells, and consequently the focus has shifted toward development of anion exchange membranes (AEMs) for anion exchange membrane fuel cells (AEMFCs). AEMFCs are low cost and use non-noble metal catalyst as cathode material (Sherazi et al. 2013). Recent reports have indicated the use of poly(vinylbenzyl chloride) grafted on ultrahigh molecular weight polyethylene (UHMWPE) powder by irradiating with gamma Co radiation. These polyelectrolyte membranes have been used in AEMFCs. Ultrahigh molecular weight polyethylene powder is highly stable in alkaline medium, shows tendency toward cross-linking when irradiated with gamma radiations, and is a low-cost material. Surface-modified UHMWPE membranes have been used as biocompatible materials for use in many biomedical applications. Surface modification of UHMWPE is done using underwater plasma polymerization technique since olefin polymers do not have any functional groups which make it relatively easier to introduce polar groups by plasma processes thereby attributing biocompatibility (Joshi et al. 2013). Polyethylene membranes have also been used in environmental monitoring applications especially the organochlorine pesticides such as lindane, aldrin, and dieldrin. It has been reported that polyethylene membranes have 24–84 times higher chemical uptake capacity as compared to the cellulose membrane. However, it is also known that the solvent retention time is low for polyethylene membranes and the rate of diffusion of chemicals is dependent not only on the molecular mass of the chemical species but also on the solubility in lipids [8].

Polyethylene Oxide

Anja Car

Department of Chemistry, University of Basel,
Basel, Switzerland

Polyethylene oxide (PEO) is a polymer prepared by polymerization reaction (polycondensation) of ethylene oxide and water catalyzed by acidic or basic catalysts (Hideshi 1995). It has two chemically synonymous names: poly(ethylene glycol) (PEG) and poly(oxyethylene) (POE) (Buchmeister 2003). PEG has tended to refer to oligomers and polymers with a molecular weight below 20,000 g/mol, PEO to polymers with a molecular weight above 20,000 g/mol, and POE to a polymer of any molecular weight with the general formula $H(OCH_2CH_2)_nOH$ (Fig. 1), commercially available over a wide range of molecular weights (<http://www.sigmaaldrich.com/materials-science/material-science-products.html>), where n is the average number of repeating oxyethylene

Polyethylene Oxide,
Fig. 1 Chemical structure
 of polyethylene oxide

groups (OCH_2CH_2) typically from 2 to few 100. The low molecular weight members from $n = 2$ to $n = 4$ are diethylene glycol, triethylene glycol, and tetraethylene glycol, respectively, which are produced as pure compounds (DOW). Increasing the number of repeating oxyethylene groups leads to products with different oligomer sizes in a broadly or narrowly defined molecular weight. For example, PEG 300 typically denotes a compound that includes a mixture of oligomers having an average molecular weight of 300 g/mol. Low molecular weight ($<1,000$ g/mol) PEGs are viscous and colorless liquids with freezing point from -10°C (diethylene glycol), while higher molecular weight PEGs (PEOs) are waxy, white solids with melting points proportional to their molecular weights up to limit of about 67°C (Bailey and Koleske 1976). These polymers are amphiphilic and soluble in water as well as in many organic solvents (e.g., methylene chloride, ethanol, toluene, acetone, and chloroform) including aromatic hydrocarbons (not aliphatic) (Zhao et al. 1998). Although PEG and PEO with different molecular weights have different physical properties (e.g., viscosity, melting point) due to chain-length effects, their chemical properties are nearly identical. Hence, they have multiple applications in different fields. They provide binding, thickening, lubricity, water retention, and film formation benefits to deliver excellent performance, such as in mining, paper, and cleaning products. Due to their nontoxic and nonirritant properties, they are broadly used as well in pharmacy, medicine, and cosmetics (Working et al. 1997; Andersen 1999). They are also thermoplastic materials that are readily calendared, extruded, injection molded, and cast, to provide even greater formulation and processing flexibility. The different forms of PEG are also available (Lapientis 2009; Fruijtier-Pöllöth 2005; Zalipsky 1995) depending on the used initiator during the polymerization process, the most common is a monofunctional methyl ether PEG (methoxypoly(ethylene glycol)), abbreviated as MPEG. PEGs are also available with different

microstructure. Branched PEGs have three to ten PEG chains emanating from a main chain; star PEGs have 10–100 PEG chains emanating from a central core group, and Comb PEGs have multiple PEG chains normally grafted to a polymer backbone.

Polymer Electrolyte Membrane Fuel Cell (PEMFC)

Enrica Fontananova
 Institute on Membrane Technology, National
 Research Council of Italy, ITM–CNR, Rende,
 Italy

Fuel cells (FCs) are electrochemical devices for the direct conversion of chemical energy into electrical energy.

Polymer Electrolyte Membrane Fuel Cell (PEMFC), Table 1 Reactions occurring in hydrogen and direct methanol polymer electrolyte membrane fuel cell (PEMFC)

	H ₂ -PEMFC	Methanol-PEMFC
Anode	$\text{H}_2 \rightarrow 2 \text{H}^+ + 2 \text{e}^-$	$\text{CH}_3\text{OH} + \text{H}_2\text{O} \rightarrow \text{CO}_2 + 6\text{H}^+ + 6\text{e}^-$
Cathode	$\frac{1}{2} \text{O}_2 + 2 \text{H}^+ + 2 \text{e}^- \rightarrow \text{H}_2\text{O}$	$\frac{3}{2} \text{O}_2 + 6\text{H}^+ + 6\text{e}^- \rightarrow 3\text{H}_2\text{O}$
Overall reaction	$\frac{1}{2} \text{O}_2 + \text{H}_2 \rightarrow \text{H}_2\text{O}$	$\text{CH}_3\text{OH} + \frac{3}{2} \text{O}_2 \rightarrow \text{CO}_2 + 2\text{H}_2\text{O}$

Unlike the classical battery, FCs do not store the energy within the chemicals internally, but they use a continuous supply of the fuel from an external storage tank. Moreover, while the electrodes in a battery react and change as a battery is charged or discharged, in a fuel cell the electrodes are catalytic.

Because FCs do not include the conversion of thermal to mechanical energy, they are not subject to the Carnot efficiency limit typical of a heat engine (e.g., steam and gas turbine) and are characterized by a high energy efficiency (Song 2002).

The primary components of a FC are: the anode, the cathode, and the ion conducting electrolyte. In a FC, the selective transport of ions through an electrolyte occurs in combination with a redox reaction.

In a Polymer Electrolyte Membrane Fuel Cell (PEMFC), the electrolyte is a polymer electrolyte membrane (PEM) which allows the transport of the protons from the anode, where they are produced in the oxidation of a fuel (usually H₂ or methanol), to the cathode, where the protons react with O₂ to produce water (Table 1).

The PEM is a cation exchange membrane and the flow of ionic charges (ideally only cations) through the membrane is balanced by the flow of electronic charge through the external circuit producing an electrical power. The only secondary products in the overall reaction are: water, heat (eventually recoverable), and CO₂, if the fuel contains carbon (e.g., methanol as fuel in direct methanol PEMFC).

The reaction at the anode is exothermic; however, it requires to overcome an activation energy barrier. Three strategies are used in FCs technology in order to improve the kinetic reaction: raising the temperature, increasing the surface electrode area, and using catalysts (usually Pt or Pt alloys).

The ion-exchange membrane is pressed with a porous electrode layer on each side and the catalyst is present at the interfaces membrane/electrode forming the so-called membrane electrode assembly (MEA).

A single PEMFC typically gives a voltage from 0.6 to 0.7 V, as a consequence, to produce a useful voltage, many cells are connected in series. Such a design is called fuel cell stack. Bipolar plates, generally made of graphite, interconnect the cathode of one cell with the anode of the next cell, serving in parallel the following functions: conducting electricity, feeding oxygen to the cathode and fuel to the anode, and channeling away wastewater and heat from the reaction sites.

Currently, the most commonly used PEMs for applications in PEMFCs are made of perfluoro-sulfonic acid polymers, such as Nafion membranes.

In the last decades, the development of new PEMs with improved properties for long-term fuel cells operations has received relevant attention. Not only perfluoropolymers but also partially fluorinated and nonfluorinated hydrocarbon, nonfluorinated aromatic, mixed matrix, and acid–base blend membranes, have been investigated. Various reviews are available which give an overview of the progress made in the development of proton-conducting polymer materials for PEMFCs (Roziere and Jones 2003; Hickner et al. 2004; Smitha et al. 2005; Tripathi and Shahi 2011; Thiam et al. 2011; Drioli and Fontananova 2012).

The properties required to the PEMs are: high proton conductivity; no electronic conductivity; low permeability to the reagent species; appropriate chemical, thermal, and mechanical stability; and acceptable costs.

The low operating temperatures (50–130 °C) and the high power density (400–1000 W/Kg) of the PEMFCs make them ideal for automotive applications, distributed power generation, and portable electronic devices (Larmine and Andrews 2000).

Although PEMFCs have recently passed the demonstration phases and have reached a partial commercialization stage (Wee 2007), there are still many issues to be addressed before large scale diffusion, including the high cost and limited durability of PEMs, the appropriate fuel production and storage.

- (PPMs), have been used for transport of solutes as an alternative to supported liquid membranes (SLMs) (Nghiem et al. 2006; Fontas et al. 2007). These membranes have also been used for metal ion uptake and sensing in ion-selective electrodes (where the ion-selective ligand can be an ionophore, an ion exchanger, or a mixture of both) and sensors (Moody et al. 1970; Scindia et al. 2002). The PIMs are known to have better stability as compared to the SLMs though the flux has been generally lower than that observed with SLMs (Paugam and Buffle 1998). However, there are some reports in which higher transport rates were observed with PIMs as compared to analogous SLMs (Kim et al. 2001). PIMs are usually made from a base polymer (such as CTA, PVC, PVDF, etc.), a carrier extractant, and a plasticizer. CTA (cellulose triacetate) and PVC (polyvinyl chloride) are some of the most widely used base polymers. While CTA works in lower acidity range, it undergoes hydrolysis at higher acidities where PVC-based PIMs have often been used. The CTA-type PIMs can have better acid/alkali resistance by increasing the chain length of the substituent though a concomitant decrease in flux may be seen when the membranes were made more hydrophobic (Gardner et al. 2004).

Organic compounds like TBP (tri-*n*-butyl phosphate) and TEHP (tri-2-ethylhexylphosphate) work both as the carrier and plasticizer and have been used for the transport of various metal ions including the actinides. However, they also suffer from the disadvantages of acid cotransport and poor decontamination from other metal ions. The PIMs, therefore, are generally made from benign plasticizers like NPOE (2-nitrophenyloctyl ether). The carrier extractant has the role of complexing with the substrate and its subsequent transport across the membrane, either by diffusional mass transfer or by a fixed-site jumping mechanism (see Scheme 1) where a threshold carrier concentration is needed (Riggs and Smith 1997). Cussler et al. have suggested a “chained carrier” model (Cussler et al. 1989) based on a percolation threshold. A model based on carrier molecule organization based on coalescence of liquid carrier-plasticizer micro-domains for the facilitated transport of the metal ions is presented in

carrier (high concentration leading to formation of micro-domains) (Reproduced with permission from Fontas et al. 2007)

the Fig. 1 below (Fontas et al. 2007). In many cases, the plasticizer reduces the glass transition temperature and imparts the PIM optimum physical characteristics required for the mobility of the ions or their complexed species. Also, the plasticizers make the PIMs less porous and homogeneous which facilitate mass transfer. While the base polymer imparts mechanical strength, the plasticizer makes the membranes flexible and facilitates the mass transfer by reducing

interactions between the polymeric strands and also by diffusion through a liquid phase similar to the SLM.

PIMs have been extensively used for the removal of toxic and heavy metals from wastewater which include anionic species like CrO_4^- (generally recovered using basic extractants like Alamine 336 or Aliquat 336) and cationic species like Pb^{2+} and Cd^{2+} (generally recovered using chelating extractants). Apart from the anionic

and cationic species transport, PIMs have also been used for neutral (Sakai et al. 2010) species transport. There have also been reports on PIM-based hollow fibers for possible large-scale processing (Kusumocahyo et al. 2006).

Polymer with Intrinsic Microporosity (PIM)

Peter M. Budd

Organic Materials Innovation Centre, School of Chemistry, University of Manchester, Manchester, UK

A polymer of intrinsic microporosity (PIM) is an amorphous, glassy polymer that contains interconnected pores of width less than 2 nm, which arise directly from the shape and rigidity of the component macromolecules (McKeown and Budd 2010). This type of polymer behaves like a microporous material or molecular sieve in a low-temperature nitrogen adsorption experiment, exhibiting high uptake at very low relative pressure. It must be emphasized that in this context, the term “microporous” refers to pores with dimensions on the molecular scale. The term “intrinsic microporosity” was originally applied to polyphenylene oxide polymers that showed evidence of an interconnected system of microcavities (Illinitch et al. 1999). It was subsequently used for polymers with backbones composed of rigid sequences linked by sites of contortion that force the backbone to twist and turn (Budd et al. 2005). These polymers possess high free volume in the solid state, because the component macromolecules cannot fill space efficiently. The prime example of a soluble, membrane-forming PIM is referred to as PIM-1 (Fig. 1).

In PIM-1, there are no single bonds in the backbone about which rotation can occur, and so it cannot undergo large-scale conformational change in the way a conventional polymer can. The spiro-center (two five-membered rings with a carbon atom in common) acts as a site of contortion, putting a bend in the chain and making it difficult for chains to align and pack together. The intrinsic microporosity, coupled with the organic nature of its backbone, gives PIM-1 a high affinity for small organic molecules, which are readily adsorbed from the vapor phase or from aqueous solution. PIM-1 is soluble in solvents such as

Polymer with Intrinsic Microporosity (PIM),

Fig. 1 Molecular structure of PIM-1 and molecular model of a fragment of PIM-1 showing its contorted shape

chloroform and tetrahydrofuran and can be processed from solution to form yellow, fluorescent, thermally stable membranes or coatings. PIM-1 membranes have been investigated for a variety of liquid, gas, and vapor separations. In pervaporation, PIM-1 exhibits organophilic character, being selective for organic species rather than water (Budd et al. 2004). In organic solvent nanofiltration, it separates smaller species from larger species (Fritsch et al. 2012). In gas separation, it helps to define the 2008 upper bound of performance for gas pairs such as CO_2/CH_4 , CO_2/N_2 , and O_2/N_2 (Robeson 2008). A variety of chemical modifications have been carried out on PIM-1 in order to tailor the transport properties.

A wide range of PIMs have been prepared, including both soluble, membrane-forming polymers and insoluble network polymers (McKeown and Budd 2010). In addition to spiro-centers, units that have been used as sites of contortion include ethanoanthracene and triptycene. PIMs are often synthesized by a step-growth polymerization involving a double nucleophilic aromatic substitution reaction between a monomer bearing pairs of hydroxyls and a monomer bearing pairs of fluorines. A recent development is the use of Tröger's base formation as a novel polymerization method (Carta et al. 2013).

Any polymer that possesses sufficient interconnected free volume as to allow the ready

uptake and transport of gasses and vapors may be regarded as having "intrinsic microporosity." This includes highly permeable, glassy polymers such as poly(1-trimethylsilyl-1-propyne) (PTMSP), in which it is the bulky trimethylsilyl side group which restricts flexibility of the backbone and forces it into a twisted shape.

Polymeric Catalytic Membranes

Enrica Fontananova

Institute on Membrane Technology, National Research Council of Italy, ITM–CNR, Rende, Italy

A polymeric catalytic membrane is a polymeric membrane with catalytic properties. The base material used to prepare the membrane is a polymer, and a catalyst is immobilized within the membrane or on its surface, conferring catalytic activity to the system.

Moreover, some polymeric membranes can have intrinsic catalytic properties towards some reactions because of the presence of specific functional chemical groups in the polymer material. This is the case of acid polymeric membranes, like Nafion (a perfluorosulfonic acid polymer), which can work as solid acid catalysts.

Polymeric catalytic membranes are usually employed when the reaction temperatures are

low (<200 °C), such as in the field of fine chemicals or when a biocatalyst is present (Vankelecom 2002).

The use of polymeric catalytic membranes has a lot of interest in the field of membrane reactors because: a much wider choice of polymeric materials is available (Ulbricht 2006), the cost of the polymer membranes is generally lower, and the preparation protocols are more reproducible in comparison with inorganic membranes.

Polymeric membranes are generally less resistant to high temperatures and aggressive chemicals than inorganic ones; however, some polymeric materials resistant under rather harsh conditions are available like: polydimethylsiloxane (PDMS), polyvinylidene fluoride (PVDF), Hyflon (a perfluoro amorphous polymer), Nafion, and polyimides (PI) (Drioli and Fontananova 2010).

Some selected examples of polymeric catalytic membranes used in membrane reactors are listed in Table 1.

In classical heterogeneous catalysis (catalyst absorbed or linked in porous polymeric or inorganic solids), the conversion and selectivity of the catalytic process is often limited by the diffusion of the reagents to the catalytic sites and the products removal from them.

On the contrary, the convective or diffusive flux in a catalytic membrane can be easily controlled and adjusted to the reaction kinetic modulating the driving force and/or the membrane structure and/or membrane material (Westermann and Melin 2009).

Moreover, in a catalytic membrane, especially if polymeric, the catalyst entrapment in the functional microstructured environment of the membrane can have a positive influence on the transition states and reaction kinetics by electronic and weak interactions, as well as by spatial restriction and transport dynamics (Fontananova and Drioli 2010).

Polymeric Magnetic Membranes

Anna Strzelewiec

Faculty of Chemistry, Silesian University of Technology, Gliwice, Poland

Synonyms

Magnetically responsive membranes

The **polymeric magnetic membranes** are polymeric membranes with dispersed granules of a permanent magnet (ferrite, praseodymium, and neodymium) or with magnetic nanoparticles (ferroferric oxides), which are intended for separation purposes (Rybak et al. 2012). As a polymer matrix the ethyl cellulose (EC) or poly(2,6-dimethyl-1,4-phenylene oxide) (PPO) can be used.

Polymeric membranes filled with neodymium powder have been successfully used for enrichment of air by oxygen. Membranes of various polymer matrices (EC and PPO) with different types of dispersed magnetic powder (ferrite, praseodymium, and neodymium) and granulation (20–32 μm , 32–50 μm) can be prepared by solution casting and evaporation. Magnetic membranes are made by casting of 3 % EC solution in 40:60 ethanol/toluene or 2.5 % PPO solution in TCE (trichloroethylene) with dispersed magnetic powders of appropriate amount: 0.5–2 g in external field (stable magnetic field with range of induction $0 \div 40$ mT) (Strzelewicz et al. 2007; Rybak et al. 2009a; Grzywna et al. 2010). In the next step membranes are removed from Petri dish and dried in 40 °C for at least 2 days before any further analysis. The membranes were stored in an exsiccator under the vacuum conditions ($p = 3$ mmHg).

The transport of the molecules through the magnetic membranes can be modeled by a diffusion with a position-dependent diffusion coefficient. Such a diffusion coefficient reflects the changes in the membrane composition along the permeation axis (Rybak et al. 2009b; Borys et al. 2011). Magnetic membranes are inhomogeneous, i.e., on the bottom (permeation side), there are the magnetic aggregates of the magnetic powder, while on the top (feed side), there is a layer of pure polymer.

Another group of magnetic membranes are polymer membranes containing magnetic nanoparticles, i.e., ferroferric oxide particles. The membranes can be prepared as described in Dudek et al. (2012), where ethyl cellulose and poly(2,6-dimethyl-1,4-phenylene oxide) were used as polymer matrix. The membranes were prepared by solution casting and evaporation.

For proper dispersion and homogenization of magnetic particles in the polymer solution, the mixture was sonicated using high-intensity ultrasound radiation. The average thickness of the obtained membranes was 25 μm . The membranes were examined for nitrogen and oxygen permeability. Detailed description of preparation and characterization of iron oxides–polymer composite membranes is given in Dudek et al. (2012).

Polymeric Membrane Characterization by PALS

Geoffrey Geise

Department of Chemical Engineering, University of Virginia, Charlottesville, VA, USA

Synonyms

PALS

The size of free volume elements in polymeric membrane materials can be related to the average lifetime of either free positrons or ortho-positronium (o-Ps) in the polymer measured using positron annihilation lifetime spectroscopy (PALS) (Mallon 2003; Hill et al. 1996, 2005; Pethrick 1997; Liao et al. 2011). Additionally, for some polymers, the average o-Ps intensity can be combined with the average o-Ps lifetime to determine the polymer's fractional free volume (FFV) (Mallon 2003; Hill et al. 2005; Pethrick 1997; Matteucci et al. 2006). In some polymers, however, positron-polymer interactions can disrupt the relationship between o-Ps intensity and the concentration of void space (or free volume elements) in the polymer (Liao et al. 2011; Jean et al. 2003; Xie et al. 2011; Hirata et al. 1997; Kobayashi et al. 2009).

Free volume information is useful for characterizing nonporous polymer membrane materials because the diffusion coefficients of penetrants in the polymer matrix are related to the polymer's free volume (Cohen and Turnbull 1959). Many studies have correlated transport properties (e.g., permeability and diffusivity) with free volume determined using PALS (Hill et al. 1996, 2005; Matteucci et al. 2006; Xie et al. 2011; Freeman and Yampolskii 2010; Ju et al. 2010; Rowe et al. 2009; Zhang et al. 2012; Chen et al. 2012; Tung et al. 2009; Merkel et al. 2002; Nagel et al. 2002; Alentiev et al. 1997; Yampolskii et al. 1994; Kim et al. 2005). These studies include polymers for gas separation membranes and liquid (e.g., desalination) membranes. These correlations further suggest that PALS is a valuable tool for characterizing polymer free volume. In addition to correlating with transport properties, PALS data have been shown to correlate with various thermal and mechanical properties of polymers (Mallon 2003; Pethrick 1997).

The average o-Ps lifetime in a polymer can be related to the average size of the polymer's free volume elements using the Tao-Eldrup model when the average free volume element radius is around or smaller than 10 Å (Mallon 2003; Pethrick 1997; Tao 1972; Eldrup et al. 1981). In general, as free volume elements become larger,

o-Ps lifetime increases (Hill et al. 2005; Pethrick 1997). Additionally, the average free positron lifetime may be related to the size of the polymer's free volume elements (Liao et al. 2011). The Tao-Eldrup model assumes that the polymer's average free volume element size can be represented by a sphere (Mallon 2003; Pethrick 1997; Tao 1972; Eldrup et al. 1981). With this assumption, the volume of a free volume element in the polymer can be calculated geometrically using the radius obtained from the Tao-Eldrup model (Mallon 2003).

Polymeric-Ceramic Catalytic Membrane

Sophie Cerneaux

UMR 5635 ENSCM, CNRS, UM, Institut Européen des Membranes, Montpellier, France

Polymer membranes and ceramic membranes are two types of membranes prepared, respectively, from organic or inorganic and metallic materials. Polymer-ceramic membranes represent a different class of membranes that combines properties of both polymer and ceramic membranes. They are often named as composite or hybrid membranes and tailored regarding the targeted application. They may consist mainly of ceramic materials modified by various kinds of polymers or polymer membranes including inorganic nanoparticles, for instance.

Catalytic membranes are developed for reactive separation processes that involve reaction and separation steps either in gas or liquid phase. Indeed, they are not only acting as filtration media but also allow the reaction to take place acting as heterogeneous catalysts.

Organic-inorganic catalytic membranes are largely applied to biodiesel production (Shi et al. 2010) for the conversion of methanol and other esterification reactions requiring a high permselectivity. A growing interest is focused on applications such as photodegradation and photocatalysis (Romanos et al. 2013) using membrane processes and coupled technologies.

Polyphenol Recovery from Olive Mill Wastewater by Membrane Separation

N. Othman

Faculty of Chemical and Energy Engineering,
Universiti Teknologi Malaysia, Skudai, Johor,
Malaysia

Polyphenols are naturally occurring compounds found largely in fruits, vegetables, cereals, and beverages. In olive processing, the production of oil is about 20 %, 30 % semisolid waste, and 50 % aqueous liquor. The liquid effluent from the olive mill wastewater (OMW) was about 0.5–1.5 m³ per 1,000 kg of olive, and the wastewater was categorized as a phenolic-rich industrial effluent. The by-products from this wastewater may become important sources of high-added value compounds, such as hydroxytyrosol or other antioxidant polyphenols. Several treatment procedures including physical, chemical, biological, or combined technologies have been tested to reduce undesirable properties of OMW and recover the value-added product. One of the promising techniques is membrane separation. Membrane separation can be divided into two modes of operation such as membrane filtration and liquid membrane separation. Membrane filtration is hybrid processes that combine pressure-driven membrane processes with adsorption processes. The efficiency of this process to remove phenol with different type of membrane is about 80 % rejection (Bódalo et al. 2009).

In ultrafiltration (UF) process, the feed stream is pumped under pressure over the surface of a membrane whereby a pressure gradient is created across the membrane, and it is split into two product streams. The pressure gradient forces the solvent, and smaller species pass through the pores of the membrane while large molecules will be retained. The retained stream is also called as retentate or concentrate which is enriched with retained macromolecules but also contains some of permeable solutes, while the rest that passes through the membrane is called as permeate. Since UF deals with large molecule separation, therefore the osmotic pressure required is relatively low (Cheryan 1998).

Micellar enhanced ultrafiltration (MEUF) can be considered as a feasible membrane alternative technique which is effective and economical for removing organic matters like polyphenol from wastewater. In view of the basic principle of MEUF process, it involves the solubilization of organic solutes in the surfactant's micelle, thus increasing the size of the solutes to be separated and eventually retained by the ultrafiltration membrane. The surfactants in the aqueous or the organic solution, above critical micelle concentration (CMC), form micelles (Elworthy et al. 1968). Most of the organic solute molecules can solubilize in the micelles. Micelles being larger in size can be rejected with the solubilized organic contaminants using a relatively porous membrane under low operating pressure. The schematic diagram of the process is shown in Fig. 1.

For the studies on MEUF of phenol, ultrafiltrations were mostly carried out using flat membranes fitted in stirred or unstirred batch cells whose effective filtration areas were below 100 cm². Works by Syamal et al. (1997) showed that the retention of phenol is not good enough and usually below 70 %. From previous study, it was found that most of the researchers used micellar enhanced ultrafiltration (MEUF) to remove phenol (Tung et al. 2002; Witek et al. 2006; Purkait et al. 2005). In MEUF systems, surfactant is used and when it is added to the polluted aqueous solution above its critical micellar concentration (CMC), it will assemble and aggregate to

Polyphenol Recovery from Olive Mill Wastewater by Membrane Separation, Fig. 1 Schematic diagram of separation of anionic and non-ionic solutes by MEUF using cationic micelles (Jadhav et al. 2011)

form micelle. The micelle can solubilize the organic solutes into its hydrophobic core or adsorb counter metal ions on its surface. The micelle forms large-size molecules and the separation is effective when passing through the small pore sizes of ultrafiltration membrane (Tung et al. 2002; Zeng et al. 2008). In the study of Witek et al. (2006), cationic surfactants, hexadecyltrimethylammonium bromide (CTAB) and anionic surfactant and dodecyl sulfate sodium salt (SDS), were used to investigate the rejection efficiency of phenol and chromium (Cr^{3+}). The results showed that rejection efficiency only achieved 35.2 % for SDS surfactant and 44.6 % for CTAB surfactant.

Another membrane separation technology is immobilized liquid membranes (ILMs), also called as supported liquid membranes (SLMs) where liquid is immobilized or impregnated in the pores of thin microporous solid support (Kislik 2010). The common types of SLM are flat (thin) sheet SLM and hollow fiber SLM. The greatest difference between SLM is its surface

area-to-volume ratio which is flat sheet and is too low compared to hollow fiber SLM (Kaushik 2008; Kislik 2010). In thin sheet SLM, the membrane is a porous polymer membrane whereby the pores are filled with organic liquid and carrier which is shown in Fig. 2. It is then set in between source and receiving phase which are being gently stirred. In hollow fiber SLM system, there are many thin fibers in which the pores are filled with organic phase running the length of the shell where the outer shell is a single nonporous material. The feed phase which contains the solutes desired is piped through the system from top to bottom, and the carriers in organic phase transport the solutes across to the receiving phase. The receiving phase is then forced out through the shell sides (Kaushik 2008).

Zidi et al. (2011) studied on extraction of phenol from aqueous acidic solutions using SLM with tri-*n*-octylphosphine oxide (TOPO) as carrier and kerosene as diluents. The results showed that 67 % of phenol was removed to the receiving phase,

Polyphenol Recovery from Olive Mill Wastewater by Membrane Separation,
Fig. 2 Schematic diagram of thin flat sheet-supported liquid membrane extraction

sodium hydroxide (NaOH) after 24 h of transport by using flat sheet SLM. However, Badgajar and Rastogi (2011) succeed to remove 92.5 % phenol after 20 h of transport by using flat sheet SLM impregnated with triglycerides (vegetable oils).

Polyphenol Recovery from Wine Wastes by Membrane Operation

Martine Mietton-Peuchot

Vine and Wine Sciences Institute, Université de BORDEAUX, Villenave d'Ornon, France

Grape wastes (pomace, seeds, lees) have been recognized as an important and inexpensive source of polyphenols. Antioxidants from residual sources could be used to increase the stability of foods by preventing lipid oxidation and to protect against oxidative damage in living systems by scavenging reactive oxygen species. In addition,

significant attention has been paid for applications of antioxidants in the food, cosmetic, and pharmaceutical industries because of similar functionality requirements for the products. Traditional wine production is accompanied by generation of waste quantities of solid wastes such as seeds and pomaces. The polyphenols are mainly anthocyanins, flavonols, phenolic acids, and stilbenes (resveratrol). Studies reported antioxidant activity of the extracts, suggesting the winery by-product for production of natural antioxidants. For the recovery of polyphenols and other functional compounds, solid–liquid extraction is widely used. The industrial batch extraction of polyphenols is performed for about 20 h at 50–60 °C. Membrane separation processes are ideal for recovering and concentrating these compounds, ensuring high quality of the extracts produced. The process should be performed in order to remove the undesirable compounds present, such as proteins and sugars, which react with the phenolic compounds potentially reducing their antioxidant activity. Moreover, the removal of microorganisms and toxic substances is highly desirable. The type and the quantity of impurities in the extract may influence the filtration mechanism and efficiency of polyphenol separation. Optimization of polyphenol purification by membrane operation requires knowledge of factors influencing the filtration flux and rejection of solutes. Filtration rate is negatively influenced by the components of natural extracts (proteins, polyphenols, pectins, and polysaccharides). Cascades of membranes with different molecular cutoffs allow for the collection of the fractions of interest. Depending on the extracts, the membrane cutoff should be adapted. Membranes with MWCO below 150 kDa may be used for concentration of polyphenols from grape seed extracts. The possibility of membrane fractionation of different phenolic compounds, contained in grape seed and grape pomace extracts, was also demonstrated. The elimination of proteins is improved with coagulation–flocculation prior to membrane separation or with pH adjustment. Proteins coagulate around their isoelectric point (pH 4) and agglomerate. Proteins are retained by the ultrafiltration membrane and polyphenols are purified in

permeation. The recovery of monomeric and oligomeric compounds may be aimed for or, alternatively, the recovery of polymeric compounds. The use of nanofiltration membranes allows for obtaining fractions enriched in phenolic compounds with low molecular mass, while a different membrane selection may allow for production of a different fraction. Control of undesirable products is achieved to a much greater extent. For example, when recovering a target extract as a permeate stream in a nanofiltration process, the exclusion of heavy metals and phytosanitary products could be assured due to the ability of these membranes to reject di- and multivalent ions and small solutes. Reverse osmosis may also be used in the final concentration. The solvent could be reused for the extraction process from wastes. Adsorption and rejection of solutes during ultrafiltration of polyphenol from grape must increase fouling resistance and reduce transmission of polyphenols to the permeation. Optimization of the process concerns the type of the membrane (polarity), pressure, pH adjustment, and volume reduction factor depending on the origin of the extracts.

Polypropylene (PP)

Fen Ran

School of Material Science and Engineering, State Key Laboratory of Advanced Processing and Recycling of Non-ferrous Metals, Lanzhou University of Technology, Lanzhou, China

Polypropylene (PP), also known as polypropylene, polypropene, propene polymers, propylene polymers, and 1-Propen, is a thermoplastic polymer made from the monomer propylene and unusually resistant to many chemical solvents, bases, and acids. The chemical structure of PP is shown in Fig. 1. The relative orientation of each methyl group relative to the methyl groups in neighboring monomer units has a strong effect on the polymer's ability to form crystals. It is the second most important plastic with revenues expected to exceed US\$ 145 billion by 2009.

Polypropylene (PP), Fig. 1 Basic structure of polypropylene

It is well known for its low cost, lightness, recyclability, easy processability, and good mechanical properties (for instance, high rigidity, impact strength, heat resistance, and durability). It is widely used in applications of packaging and labeling, textiles, stationery, plastic parts and reusable containers, laboratory equipment, loudspeakers, automotive components, and polymer banknotes. Also it is widely used to high volume plastic materials. It becomes more resistant to high temperatures and stiffer at lower density when not subjected to mechanical stress, which is the main advantage of its application in construction materials and automobile industry, as well.

Based on the tacticity, it is divided into three types: isotactic polypropylene, atactic polypropylene, and syndiotactic polypropylene (Ray and Robert 2010). PP was first synthesized to a crystalline isotactic polymer by Giulio Natta as well as by the German Karl Rehn in March 1954. This pioneering discovery led to a large-scale commercial production of isotactic polypropylene by the Italian firm Montecatini from 1957 onward. Syndiotactic PP was also first polymerized by Natta and his coworkers. Crystals, such as Ziegler-Natta catalysts and metallocene catalysts, is very important for synthesis. The most representative manufacturing processes to produce PP are hydrocarbon slurry or suspension, bulk (or called bulk slurry), and gas phase. Hydrocarbon slurry uses a liquid inert hydrocarbon diluent in the reactor to facilitate transfer of propylene to the catalyst, the removal of heat from the system, the deactivation/removal of the catalyst, as well as dissolving the atactic polymer. The range of grades that could be produced was very limited. Bulk uses liquid propylene instead of liquid inert hydrocarbon diluent. The polymer does not

dissolve into a diluent, but rather rides on the liquid propylene. The formed polymer is withdrawn and any unreacted monomer is flashed off. Gas phase uses gaseous propylene in contact with the solid catalyst, resulting in a fluidized bed medium.

Melt processing of PP can be achieved via extrusion and molding. Common extrusion methods include production of melt-blown and spun-bond fibers to form long rolls for future conversion into a wide range of useful products, such as face masks, filters, diapers, and wipes. The most common shaping technique is injection stretch, which is used for parts such as cups, cutlery, vials, caps, containers, housewares, and automotive parts such as batteries. The related techniques of blow molding and injection stretch blow molding are also used, which involve both extrusion and molding (Moore 1996).

It is used in the manufacturing piping systems. This material is often chosen for its resistance to corrosion and chemical leaching. Many plastic items for medical or laboratory use can be made from PP because it can withstand the heat in an autoclave. Biaxially oriented PP is used to make a wide variety of materials including clear bags. It is widely used in ropes, distinctive because they are light enough to float in water. It is also used as alternative polyvinyl chloride as insulation for electrical cables. It is used in particular roofing membranes as the waterproofing top layer of single-ply systems as opposed to modified-bit systems. It is used for the production of stationery folders, packaging, and storage boxes. Expanded PP is a foam form of PP, used in model aircraft and other radio-controlled vehicles by hobbyists. PP is used in the manufacture of loudspeaker drive units.

PP can be fabricated into PP membranes with absolute pore size ratings and used in various aqueous and organic solvent samples for applications of aqueous and organic solvent, ion chromatography, total digest for heavy metals, separator materials for batteries, and so on. The Environment Working Group classifies PP as of low to moderate hazard. PP is recyclable and has the number 5 as its resin identification code.

Polypropylene Membrane

Fen Ran

School of Material Science and Engineering, State Key Laboratory of Advanced Processing and Recycling of Non-ferrous Metals, Lanzhou University of Technology, Lanzhou, China

Polypropylene membrane (PP membrane) is one of the most important polymeric membranes and is widely used in the removal of bacteria, beer and wine clarification, wastewater treatment, oil–water separation, blood oxygenation, as a separator for batteries, etc. PP membrane is a hydrophobic membrane and it is flexible, durable, unbreakable, nontoxic, and uniform in strength. The polypropylene membrane has excellent chemical resistance, acid and alkali resistance, and solvent resistance. It can be used at high temperatures and to ensure a good filter velocity and flux. It could suitably support for cell growth, filter medium, solution disinfection, and other biological research because of no media loss and contamination. It has a long using life and good thermal stability. It is also good for gas filtration field.

When PP membrane is extruded and stretched in both the machine direction and across machine direction, it is called biaxially oriented polypropylene (abbreviated as BOPP). Biaxial orientation increases strength and clarity. BOPP membranes often have a thickness of 20 μm . Most of BOPP membranes are manufactured by conventional longitudinal–transverse sequential biaxial stretching method. In conventional longitudinal–transverse sequential biaxial stretching method, polymer is melted by an extruder, filtered, extruded from a slit die, and wound around a

metal drum to prepare a cooled and solidified unstretched membrane. The unstretched membrane is passed between rolls of different rotating speeds and is stretched in the longitudinal direction. The membrane is then fed into a tenter, is stretched in the transverse direction, and is heat-set, cooled, and wound. This process is the typical process for manufacturing biaxially stretched polypropylene membranes (Masuda et al. 2010). BOPP is widely used as a packaging material for packaging products such as snack foods, fresh produce, and confectionery. It is easy to coat, print, and laminate to give the required appearance and properties for use as a packaging material. This process is normally called converting. It is normally produced in large rolls, which are slit on slitting machines into smaller rolls for use on packaging machines.

Casting PP (abbreviated as CPP) membrane, also known as the non-stretched PP membrane, is produced by casting PP membrane extrusion process. Relative to the polyethylene membrane, polyester membrane, and PVC membrane, CPP membrane is not only less expensive but also has a high gloss, has good flatness, has aspect of the performance balance, is easy to seal, and has easy processing of metal and other characteristics. And CPP membrane may be corona treated aluminum, printing or with other materials; therefore, CPP membrane is widely used as food, daily necessities, and electronic packaging materials.

PP membrane is used as battery separator that is among the most highly engineered and critical components of lithium battery systems. They provide a barrier between the anode and the cathode while enabling the exchange of lithium ions from one side of the battery to the other. Separation mechanism of PP membrane for lithium-ion battery is shown in Fig. 1.

Because of fundamental engineering and economic advantages over competing separation technologies, PP membranes are also used for CO_2 capture from power plant emissions. PP membrane with 71 % porosity is also used as proton exchange membrane fuel cell. It is prepared in supercritical CO_2 with high solubility to obtain a porous having high porosity and mechanical strength without forming a high amount of

Polyvinylidene Fluoride (PVDF)

Fu Liu

Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, Ningbo, China

PVDF is a semicrystalline polymer with the repeating unit of $-\text{CH}_2-\text{CF}_2-$. The commercial PVDF is generally produced by the polymerization of vinylidene difluoride in emulsion or suspension. PVDF chains can crystallize into at least four distinct phases or forms, which are α (form II), β (form I), γ (form III), and δ (form IV). PVDF has excellent resistance to most solvents, acids, bases, and heat. It can be dissolved in some strong polar aprotic solvents, e.g., dimethylacetamide (DMAc), dimethylformamide (DMF), *N*-methyl-2-pyrrolidone (NMP), dimethyl sulfoxide (DMSO), triethyl phosphate (TEP), etc. It has a low critical surface tension of 25–28.5 dyn/cm. The melting temperature is around 160–180 °C, and the glass transition temperature is around 41 °C. It can be used in the coating, insulator, chemical, semiconductor, medical, and defense industries, lithium-ion batteries, as well as porous membranes for filtration and purification, etc. (Liu et al. 2011).

Polyvinylidene Fluoride Membranes

Fu Liu

Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, Ningbo, China

Polyvinylidene fluoride (PVDF) membrane usually refers to a porous microfiltration or ultrafiltration membrane with the pore size distribution of 0.01–0.4 μm . Typically, it is fabricated via phase inversion including immersion precipitation and thermally induced phase separation, besides non-solvent assisted thermally induced phase separation (Nat-ips), or supercritical CO_2 (SCCO_2)-induced phase separation was recently developed for PVDF membrane formation. PVDF membranes have been extensively applied in microfiltration and ultrafiltration for general separation purposes due to its outstanding properties, such as high mechanical strength, thermal stability, chemical resistance, and high hydrophobicity, and are currently being explored as potential candidates in the applications of membrane contactor, membrane distillation, CO_2 separation, and hemodialysis. PVDF membrane can be produced and assembled into flat sheet or hollow fiber module, which has been widely used as a mainstream membrane bioreactor (MBR) material in wastewater treatment, submerged ultrafiltration, and pretreatment of seawater desalination (Liu et al. 2011, 2012).

Pore Forming Agent

Jiahui Shao

School of Environmental Science and Engineering, Shanghai Jiao Tong University, Shanghai, China

High porosity, suitable pore size, and pore size distribution are essential for the usefulness of the membranes. In order to improve the membrane permeation properties, a commonly adopted approach is adding pore-forming agents (additives) in casting solution through adjusting the membrane structure. Based on the fundamental concept that the sublayer of asymmetric polymeric membrane is strongly influenced by the additives and that of their aggregates which are in the casting solution, there is always an ongoing research in exploring new suitable additives for membrane making (Mohanty and Purkait 2011). It is generally believed that pore-forming agents increase the polymer dope viscosity, create a spongy membrane structure by prevention of macrovoid formation, enhance the pore interconnectivity when added in appropriate amounts, or speed up the displacement of solvent with non-solvent in the coagulation bath, that is, enhance the liquid-liquid demixing process during precipitation of the dope solution, and therefore the formation of larger pores is favored. However, the mechanical strength of these membranes normally decreases, and pore-forming agents may eventually leach out from the resulting membrane due to their relative small sizes and their high affinity to the water (Liu et al. 2011).

Pore-forming agents are mainly divided into three categories: (1) low molecular weight inorganic salts; (2) high molecular weight additives, known as polymeric additives; and (3) other types of additives. Sometimes, mixture of more than one agent is used to provide the membrane with appropriate permeation properties:

1. Low molecular weight inorganic salts: These inorganic salts include lithium chloride (LiCl), zinc chloride (ZnCl_2), magnesium chloride

(MgCl_2), calcium chloride (CaCl_2), lithium perchlorate (LiClO_4), magnesium perchlorate ($\text{Mg}(\text{ClO}_4)_2$), calcium perchlorate ($\text{Ca}(\text{ClO}_4)_2$), and others. Currently, lithium chloride (LiCl) is commonly used. It is generally believed that ion-dipole interactions between metal ions and membrane polymers enhance the demixing process and form more and larger pores (Mohanty and Purkait 2011). With these inorganic salts added, the membrane porosity increases while the mean pore size is almost constant, which causes the water flux to significantly increase without causing an obvious drop in solution rejection.

2. Polymeric additives: Polymeric additives are normally hydrophilic in nature. These additives not only enhance the permeation properties of the membrane but also increase its hydrophilicity. Polyvinylpyrrolidone (PVP) and poly(ethylene glycol) (PEG) are commonly used and studied. The addition of polymeric membranes promotes non-solvent flux upon immersion in the coagulation bath, thus favoring the formation of large finger-like macrovoids. The membrane permeation properties change with the concentration and molecular weight of the polymer added. Generally, as the concentration of adding polymer increases, the membrane porosity and permeation flux increase. The membrane porosity and permeation flux normally also increase with increasing molecular weight of the polymer (Mohanty and Purkait 2011); Liu et al. 2011). However, the solute rejection decreases but normally does not have significant reduction.
3. Other types of additives: Other frequently used pore-forming agents include glycerol, water, alcohol, formamide, and polyethylene oxide (PEO) or the mixture of them.

Pore Model

Vasilis Burganos

Institute of Chemical Engineering Sciences,
Foundation for Research and Technology –
Hellas, FORTH/ICE-HT, Patras, Hellas

A model that involves a set or a network of pores to represent the void phase in the interior of porous materials. It is used in the context of pore structure characterization and as a structural basis for the prediction of transport properties. Traditionally used pore model types are the parallel pore model (Wheeler 1955), the random pore model (Wakao and Smith 1962) or dual porosity model, the cavity-neck model (Conner et al. 1983), and numerous variations. Because of the explicit representation of the void space that is offered by a pore model, major topological and geometrical features of the pore structure can be revealed or identified. The former relate mainly to pore connectivity as quantified by quantities like coordination number, genus per unit volume, etc., whereas the latter include pore shape, pore volume, pore size distribution, internal surface area per unit of volume, pore roughness, etc. These features can be extracted from individual or combined experimental techniques that can be divided into static (mercury porosimetry, gas adsorption/desorption, calorimetry, nuclear magnetic resonance, radiation scattering, wave propagation, etc.) and dynamic (liquid displacement, fluid flow). In fact, pore models play an important role in the physically meaningful and explicit interpretation of the data that are produced by these techniques. Once a pore model is set up, investigations of transport phenomena in the interior of porous materials in a direct manner are greatly facilitated for the prediction of effective transport properties and for the identification of underlying mechanisms. Notable examples are diffusion of single species and multicomponent mixtures, single and multiphase flow, heat and ion conduction, convective diffusion and conduction, transport in catalytic or non-catalytic fluid-solid reaction systems accompanied by pore

structure evolution, etc. In the presence of chemical reaction, as, for instance, in membrane reactors, access to and removal from the reaction front of reactants and products are affected significantly by the pore structure features, and the use of a pore model that is temporally changing is highly appreciated. The study of wetting phenomena is also greatly facilitated by the employment of pore models both for the purpose of structure characterization and for the theoretical modeling of capillary phenomena during immiscible and miscible displacement in porous media with the objective to predict percolation and breakthrough conditions. Thanks to this direct usefulness of pore models in the identification of structural features and in the prediction of transport properties and the fact that membrane separation is based on selective transport, pore models enjoy strong utilization in membrane science and engineering. More specifically, pore models are used for the understanding of the role of the membrane pore structure in the target separation process, for the elucidation of the relationship between structure and transport, and for the design of new or modified membranes for specific separations. Pore models are a major design component in numerous membrane processes, including, most notably, gas separation, ultrafiltration, microfiltration, pervaporation, membrane contactors, membrane distillation, etc. Flux equations at the individual pore scale and at the pore network scale have been developed (Maxwell-Stefan equations, dusty gas equations) that describe the relationship between driving forces and resulting fluxes of the different species (Jackson 1977). The former include gradients of species concentration, partial pressure, chemical potential, pressure, temperature, etc. For pore networks that can be characterized adequately by a constant or a mean coordination number, effective medium treatments are available that homogenize the transport property of a distributed pore size network and with the help of the smooth field approximation can offer an excellent estimate of the overall transport of the pore structure (Burganos and Sotirchos 1987). In the case of variable connectivity of the pore network,

Pore Model, Fig. 1 Pore segment identification process to produce a cavity-neck model

standard network solutions are available in the form of numerical algorithms that practically express the continuity condition at pore intersections (Fig. 1).

Pore-Through-Flow Catalytic Membrane

► Contactor-Type Catalytic Membrane Reactor

Porous Functional Membranes

Bijay P. Tripathi

Department of Nanostructured Materials, Leibniz
Institute of Polymer Research Dresden, Dresden,
Germany

A membrane is an interphase between two adjacent phases acting as a selective barrier, regulating the transport of substances between the two compartments. The main advantages of membrane technology as compared with other unit operations in (bio)chemical engineering are related to this unique separation principle, i.e., the transport selectivity of the membrane (Ulbricht et al. 2006). With an annual market growth rate above 10 %, membranes now play a leading role in many industries including water treatment, energy, electronics, health care, and agrobusiness. The importance of membrane technology is emphasized by the fact that one of the major challenges of this century is the provision of safe drinking water for a growing population. The most promising solutions to this problem which are environmental and energy friendly could come from new filtration membranes tailored at nanoscale (Elimelech et al. 2011). In the past decade, membrane separations have gained high technical relevance in a wide range of applications, from water purification to medical applications. Membrane-based filtration processes, such as reverse osmosis and ultra- or nanofiltration, are commonly used in desalination, waste-water treatment, and power generation. Major problems associated with membrane-based separation processes include fouling (chemical and biological) and high pressure loss, which decrease the efficiency of the filtration, decrease membrane lifetime, and increase operation costs. Main challenges for the development of novel filtration membranes are a narrow and adjustable pore-size distribution and a thin barrier layer so that the trade-off between

high selectivity and high flux could be overcome. Several polymeric materials are being studied in an effort to improve membrane performance. Generally, filtration membranes are derived from membrane-forming materials with better stability and durability such as polyamide, poly(ether sulfone), polyvinylidene fluoride, polyethylene terephthalate, polytetrafluoroethylene, etc. Membranes based on these polymeric materials are mainly prepared by either phase inversion process or track-etching process. The scanning electron microscopy image of track-etched and phase inversion membrane is given in Fig. 1.

However, despite many benefits, these materials suffer with relatively high hydrophobic nature which is a considerable limitation in water filtration application because it does not allow water permeation at significant rate. Suitable functionalization and surface modification have been reported as material design strategies for increasing the hydrophilicity of these membranes. To increase the hydrophilicity, various additives are used in the fabrication of membranes that can be broadly categorized into the polymeric additive groups of polyvinylpyrrolidone (PVP), poly(ethylene glycol) (PEG), and weak solvents such as glycerol. The addition of PVP and PEG has become a standard method to obtain “hydrophilized” membranes. To avoid the leaching-out problem, covalent grafting and cross-linking with additives have been suggested (Tripathi et al. 2014; Yang and Gleason 2012).

Recently a new type of functional and environmental stimuli-responsive membranes has been proposed, which can control the water permeability and solute rejection responding to various stimuli, such as pH, salt, temperature, solute, special chemical substances, and so on. With nanoscale pores, high porosity, narrow pore-size distributions, ability for selective functionalization, and tunable chemical and mechanical properties, block copolymers hold tremendous potential as robust, efficient, and highly selective separation membranes (Tripathi et al. 2013; Nunes and Car 2013). Block copolymers are

promising materials for fabricating high throughput and improved amphiphilic filtration membranes. The self-assembly of block polymers can produce membranes with narrow pore-size distributions and high porosities, an advantage over current filtration membranes with polydisperse pore sizes. Although nanoporous membranes based on block copolymers offer great chemical tunability, limitations in thermal stability, mechanical performance, and solvent resistance can thwart even broader applications (Fig. 2).

Porous Membranes

Fabio Bazzarelli, Lidietta Giorno and Emma Piacentini
Institute on Membrane Technology, National Research Council of Italy, ITM–CNR, Rende, Italy

Porous membranes consist of a solid matrix with defined holes or pores which have diameters ranging from less than 2 nm to more than 20 μm (Strathmann et al. 2006). The separation of solutes by porous membranes is mainly a function of molecular size and membrane pore size distribution (Baker 2004). These membranes are used to separate colloid particles or large molecular weight solutes from the solvent. High selectivity can be obtained when the solute size or particle size is relatively larger than the pore size of the membrane. Using the definition of pore size as adopted by the IUPAC (Sing et al. 1985), the porous membrane with average pore diameters larger than 50 nm is classified as macroporous, and those with average pore diameters in intermediate range between 2 and 50 nm are classified as

mesoporous. Membrane with average pore diameters between 2 and 0.2 nm is classified as microporous. Below 0.2 nm, membranes are classified as nonporous (or dense). Table 1 summarizes membrane processes based on macroporous, mesoporous, and microporous membranes and their separation mechanism and transport model.

Based on the type of structure, membranes can be distinguished in symmetric, in which the pore diameters do not vary over the membrane cross section or asymmetric. In this case, the pore diameters increase from one side of the membrane to the other side.

A wide range of inorganic materials such as ceramics, glasses, metals, or organic including different classes of polymers can be used to fabricate porous membrane. The material selection and pore size of the membranes depend on the application for which it would be used.

The membrane conformation can be flat sheet assembled in spiral wound module or tubular. On the basis of the diameters, tubular membrane is classified as follows (Mulder 1996):

1. Hollow fiber membrane (diameter <0.5 mm)
2. Capillary (diameter 0.5–5 mm)
3. Tubular (diameter >5 mm).

The membrane performance depends on important parameters such as crystallinity of the membrane-based polymer, porous structure, hydrophobicity/hydrophilicity, surface roughness, and surface charge.

The selection of a technique for polymeric membrane fabrication depends on a choice of

Porous Membranes, Table 1 Overview of membrane processes based on porous membrane and transport model

Process	Type of membrane	Applied driving force	Separation mechanism mode of transport
Microfiltration	Macroporous	Hydrostatic pressure	Size exclusion, convection
Membrane distillation	Macroporous	Temperature difference partial pressure gradient	Diffusion
Ultrafiltration	Macroporous, Mesoporous	Hydrostatic pressure	Size exclusion, convection
Nanofiltration	Mesoporous	Hydrostatic pressure concentration gradient	Size exclusion, electrostatic interactions, solution/diffusion
Dialysis	Microporous	Concentration gradient	Diffusion
Gas separation	Microporous (or dense)	Hydrostatic pressure concentration gradient	Knudsen diffusion (solution/diffusion)

Porous Membranes,

Fig. 1 Schematic drawing illustrating the casting solution on support using doctor blade

polymer and desired structure of the membrane. The techniques commonly used for preparation of polymeric membranes include phase inversion, sintering, stretching, track etching, and template leaching (Lalia et al. 2013, Strathmann et al. 2006).

1. *Phase inversion process* can be described as a demixing process whereby the initially homogeneous polymer solution is transformed in a controlled manner from a liquid to a solid state. Figure 1 schematic drawing illustrating the casting solution on support using doctor blade is reported.

The polymer precipitation can be accomplished in several ways, namely:

- (a) *Immersion precipitation* (or non-solvent-induced phase separation NIPS). A process where a polymer solution is casted on a suitable support and then immersed in a coagulation bath containing a non-solvent, where an exchange of solvent and non-solvent takes place and the membrane is formed. The non-solvent-induced phase separation is obtained by diffusion of the solvent into the non-solvent
- (b) *Thermal precipitation* (or thermally induced phase separation TIPS). This method is based on the phenomenon that the solvent quality usually decreases when the temperature is decreased. After demixing is induced, the solvent is removed by extraction, evaporation, or freeze drying. The temperature-induced phase separation is also applicable for the preparation of porous membrane from glass mixtures and metal in combination with leaching procedure.

- (c) *Precipitation by solvent evaporation*. The polymer solution is made in a solvent or in a mixture of a volatile non-solvent and the solvent. Then the polymer solution is casted on a flat porous substrate using a doctor blade technique. When the volatile solvent evaporates from the casted solution, a thin polymer film is formed on the porous support.
- (d) *Precipitation from vapor phase*. The polymer solution is exposed to an atmosphere containing a non-solvent (typically water); absorption of non-solvent causes demixing/precipitation.

Phase inversion technique can be used to produce porous membrane with a large variety of pore size by varying the type of polymer, polymer concentration, composition of cast solution, precipitation medium, and precipitation temperature.

2. *Sintering process* allows to obtain porous membrane from organic materials and from inorganic materials. A powder of certain size particles is pressed into a film or plate and sintered just below the melting point of materials. The particles size of the powder is the main parameter determining the pore size of the membrane.
3. In the *stretching technique*, the polymer powder is extruded at temperature close to its melting point coupled with a rapid drawdown. After annealing and cooling, the extruded film is stretched perpendicular to the direction of drawing. This leads to partial fracture of the film, and relatively uniform pores are obtained.
4. In the *track etching*, a nonporous polymeric film is irradiated with energetic heavy ions leading to the formation of linear damaged tracks across the irradiated polymeric film.

Then the film is immersed in an acid or alkaline bath, and the polymer is etched away along the tracks to form uniform cylindrical pore with narrow distribution.

5. *Template leaching* is suitable for preparing porous membrane from polymers which do not dissolve in common organic solvent and also from glasses, metals, and ceramics. In this technique, a homogeneous film is prepared from a mixture of membrane material matrix and leachable component. The leachable component can be a soluble low-molecular-weight solid and liquid, or even a polymeric material. After the film has been prepared, the leachable is removed by suitable chemical treatment.

The techniques commonly used for the preparation of polymeric inorganic membranes include sintering technique and template leaching, slip casting, and sol-gel process.

1. In the *slip casting*, aluminum oxide suspension is mixed with organic polymer and poured in a mold or extruded in the desired shape as flat sheet, tube, or capillary, dried and sintered at elevated temperature. One surface of the support structure is then coated with finer particles, dried, and sintered again.
2. In the *sol-gel process*, metal oxide such as aluminum oxide is dissolved in alcohol and then hydrolyzed and precipitated by addition of excess water at elevated temperature to form a colloid solution. This solution is cooled to form gel, which is then coated on support and sintered.

Another sol-gel route involves the partial hydrolysis of metal alkoxide in alcohol solution by addition of minimum of water. The active hydroxyl groups of the alkoxide react with each other and form an inorganic/organic polymer. It is coated on the support and then dried, sintered and further cross-linked to obtain a porous structure.

Australia

Institute of Physical Chemistry, University of
Muenster, Muenster, North Rhine–Westphalia,
Germany

Porous silicon (pSi), as its name suggests, is bulk silicon that has been etched by some means to form pits (pores) on its surface. Porous silicon is produced through the chemical, photochemical, or electrochemical etching of flat, crystalline silicon with fluoride solutions (Canham 1997; Schmeltzer and Buriak 2005). Galvanostatic anodization of flat silicon is the method most often employed to fabricate pSi because it provides greater reliability and selectivity to the surface produced. Aqueous hydrofluoric acid (HF) in ethanol is a common etchant used. The ethanol component is used to reduce the surface tension of the etching solution and allow full wetting of the silicon substrate (Schmeltzer and Buriak 2005). The etching process is undertaken at room temperature in a specially designed etching cell (Fig. 1) made of the fluoride-resistant Teflon. The pores produced are highly one dimensional and are of random shape (Fig. 2).

Porous Silicon,

Fig. 1 Schematic of the etching cell used for the anodic etching of silicon

Porous Silicon, Fig. 2 SEM images of (a) top-down view of porous silicon showing the irregularly shaped pores produced and (b) side-on view of porous silicon still supported on bulk silicon (at *bottom*)

The fabricated pores formed can be in a range of tuneable sizes from micropores (<5 nm) to mesopores (5–50 nm) to macropores (>50 nm). The pore morphology is affected by the current density, silicon dopant (e.g., boron or phosphorus density), illumination, and HF concentration during etching (Canham 1997). Increasing the current density causes lateral etching and hence increasing diameter. Increasing HF concentration increases the number of F^- anions at the solution-surface interface resulting in a quicker reaction between the F^- anion and the holes, producing pores with smaller diameters and increasing porosity (Canham 1997). Etching

time affects the depth of the etch with longer times yielding deeper pores (Lehmann 2002).

HF etching of silicon yields a Si-H-terminated surface. These surfaces can be modified using a number of different chemical reactions; the most common are hydrosilylation and oxidation followed by from which a range of surface chemistries can be achieved (Schmeltzer and Buriak 2005; Jane et al. 2009). Porous silicon is an ideal biomaterial due to its biodegradability, large internal surface area, and biocompatibility that has found application in biosensing, tissue engineering, and drug delivery applications (Anglin et al. 2004; Jane et al. 2009).

Porous Silicon,

Fig. 3 Photographs of pSi membranes (a) attached to the silicon wafer and (b) lifted off the silicon wafer

Porous silicon membranes are thin layers of pSi with pores open at either end. Fabrication of pSi membranes has been achieved by etching through an entire Si wafer (Searson 1991), by etching a thin layer of pSi followed by macroscopically etching from the back side (Cruz et al. 2005), and by the “lift-off” of a pSi layer (Velleman et al. 2010). The “lift-off” procedure involves the etching of a pSi film to a desired depth followed by the electropolishing of the bottom of the film to liberate it from the bulk Si. Electropolishing is achieved by increasing the current density and/or decreasing the HF concentration. The brittle nature of pSi membranes makes them unsuitable for commercial membrane applications. However, the small pores make interesting systems for fundamental transport investigations such as gas (Solanki et al. 2004; Cruz et al. 2005) and fluid (Velleman et al. 2010, Fig. 3).

Porous Stainless Steel Hollow Fibers

Bart Michiels
Sustainable Materials Management, Flemish
Institute for Technological Research – VITO,
Mol, Belgium

Inorganic membranes are gaining much interest due to their high resistance against abrasion, temperature, and chemicals. They can be used for processes involving corrosive environments

Porous Stainless Steel Hollow Fibers, Fig. 1 Porous stainless steel hollow fibers produced using dry-wet spinning (a) and extrusion (b) and robotic fiber deposition (c)

and/or high temperatures, where polymeric membranes tend to fail. A subgroup of these inorganic membranes is the metallic membranes of which the stainless steel membranes are the largest group. They are not brittle, so they show a better cracking resistance; they have a high mechanical strength and allow for rapid thermal cycling. Furthermore, they can be welded or brazed, if needed, to other metallic components. These metallic membranes are mainly used as membrane supports but also have applications in microfiltration, ultrafiltration, and gas separation at high temperatures.

In contrast to polymer membranes, the most common geometry for inorganic membranes is flat sheets and tubular membranes. However, some recent developments focus on the preparation of stainless steel tubular membranes with small diameters (<5 mm), also referred to as capillaries or hollow fibers. The big advantage of these geometries is the high surface-to-volume ratio and the smaller sealing area.

Preparation

Stainless steel hollow fibers made with different processes are shown in Fig. 1. The most common techniques are either dry-wet spinning or extrusion. Both techniques start from a fine stainless steel powder which is mixed with some organic additives and/or solvents depending on the process. The mixture is then shaped into a green

hollow fiber. Afterward, the organic additives are removed during a calcination step, and the fibers obtain their final properties during a sintering step.

Spinning is a common technique to produce polymeric, ceramic, and metallic hollow fiber or capillary membranes. The technique has been originally been developed by Loeb and Sourirajan for RO membranes (Loeb and Sourirajan 1962). A mixture containing polymer, solvent, and stainless steel particles is pressed through a spinneret and subsequently immersed in a coagulation bath which contains a non-solvent. The exchange of solvent in the mixture and non-solvent in the coagulation bath induces a phase separation into a polymer-lean phase and polymer-rich phase. The polymer-rich phase solidifies and fixates the stainless steel particles.

Properties

For inorganic membranes, two kinds of porous fiber morphologies can be obtained using dry-wet spinning depending upon the process parameters, i.e., fingerlike voids (large pores) and a spongelike structure (smaller pores). This is also valid for stainless steel fibers. Figure 2 shows the SEM image of stainless steel fibers containing both morphologies, the large fingerlike pores on the inside and the spongelike pores on the outside (Luiten-Olieman et al. 2011b; 2012). Their ratio can be tuned in the fibers depending on the speed of the phase inversion of the polymer mixture. This can be done by playing altering the

Porous Stainless Steel Hollow Fibers, Fig. 2 SEM images of stainless steel fiber derived from 70 wt% particle-loaded spinning mixture: (a) green compact; (b)

sintered at 1100 °C; (c) green compact, higher magnification; (d) sintered at 1100 °C, higher magnification (Luiten-Olieman et al. 2011a)

Porous Stainless Steel Hollow Fibers, Fig. 3 SEM images of the stainless steel hollow fibers sintered at different temperatures for 0.5 h. From left to right: 1000 °C,

1100 °C, 1200 °C, and 1300 °C. From top to bottom: close-up of the cross section and of the outer surface (Michielsens et al. 2013)

composition of the bore liquid and/or coagulation bad, the air-gap length, etc.

Another way to control the porosity is by adapting the heat treatment of the hollow fiber. Sintering at higher temperatures results in less porous morphologies. Figure 3 shows the effect of increasing sintering temperatures on a stainless

steel fiber. At low temperatures, almost no neck formation is visible, while an almost dense structure is obtained at high sintering temperatures.

The pore morphology and size both have an effect on the properties of the stainless steel hollow fibers. Fibers with a more open pore structure generally shows larger flux in case across the membrane.

However, the mechanical strength is generally better for the structures with spongelike morphologies and a low porosity. Therefore, depending on the intended application, a choice will have to be made between morphology with good flux properties and sufficient mechanical strength.

- (Schrader and Jean 1988; Jean et al. 2003). These lifetime and intensity data can provide information about the molecular-scale nature of the material (Jean et al. 2003; Pethrick 1997). Typically, PALS is performed by surrounding a positron source (e.g., $^{22}\text{NaCl}$) with the sample of interest and placing it between two detectors (Jean et al. 2003). One detector is sensitive to the photon that is produced when the positron forms, and the other detector is sensitive to the photon that is emitted when the positron annihilates (Jean et al. 2003). The signals from these detectors can be processed and sorted to determine the length of time between each formation and annihilation event (Schrader and Jean 1988; Jean et al. 2003; Pethrick 1997). This information can be further processed and analyzed to determine the average lifetime of each positron species that forms and annihilates in the sample (Schrader and Jean 1988; Jean et al. 2003; Pethrick 1997). Additionally, the intensity or the concentration of each positron species that forms and annihilates in the sample can be determined, and these data can provide additional information about the nature of the sample.

The lifetime of a positron depends on the positron's electronic state and its environment (Schrader and Jean 1988; Jean et al. 2003; Pethrick 1997). When a positron combines with an electron to form positronium, para-positronium (p-Ps) is formed if the spin states of the electron and positron are parallel, and ortho-positronium (o-Ps) is formed when the spin states of the electron and positron are antiparallel (Pethrick 1997). The lifetime of p-Ps is 0.125 ns, and in molecular media the average o-Ps lifetime typically falls in the range of 0.5–5 ns (Pethrick 1997). The lifetime of free positrons in molecular media is typically around 0.4 ns (Pethrick 1997).

Because the average lifetimes of free positrons and o-Ps in molecular media are sensitive to their environment, these lifetimes can be related to the size of molecular-scale void space or free volume in the media (Pethrick 1997; Mallon 2003; Ju et al. 2010; Xie et al. 2011; Hill et al. 1996, 2005; Rowe et al. 2009; Tao 1972; Eldrup et al. 1981; Zhang et al. 2012; Freeman and Yampolskii 2010; Liao et al. 2011; Chen

Positron Annihilation Lifetime Spectroscopy (PALS)

Geoffrey Geise

Synonyms

PALS

Positron annihilation lifetime spectroscopy is used to determine the average lifetimes and intensities of positron species in molecular media

et al. 2012). The small size of positrons and positronium allows PALS to probe angstrom-scale void spaces in molecular media (Pethrick 1997; Hill et al. 2005). Additionally, in some materials, the intensity of o-Ps can be related to the concentration of void spaces in the material, but this relationship can be disrupted by the chemical nature of the sample (Pethrick 1997; Xie et al. 2011; Kobayashi et al. 2009). This feature is useful for studying nonporous membranes for both gas and liquid separations because free volume in these materials is related to the diffusion of small molecules through the material (Ju et al. 2010; Xie et al. 2011; Hill et al. 1996, 2005; Rowe et al. 2009; Zhang et al. 2012; Freeman and Yampolskii 2010; Chen et al. 2012; Yampol'skii et al. 2006; Cohen and Turnbull 1959; Matteucci et al. 2006).

Synonyms

[Positron annihilation technique](#)

Positron annihilation spectroscopy (PAS) is a tool for studying positron and positronium chemistry

(Schrader and Jean 1988; Jean et al. 2003; Pethrick 1997). Positrons, which are positively charged electrons, interact with molecular media to form a variety of different electronic states, and these species subsequently annihilate (Schrader and Jean 1988; Jean et al. 2003). Positronium, which is a neutral atom composed of a positron and an electron, can also interact with molecular media and subsequently annihilate (Jean et al. 2003). In addition to forming positronium, positrons can also interact with molecules in molecular media (Schrader and Jean 1988; Jean et al. 2003). Positron-electron annihilation produces photons, and PAS measures the energies and momenta of these photons (Pethrick 1997). Furthermore, these photons can be detected as single events, and this information can be used to determine the photon's emission time and the lifetime of the positron or positronium atom (a separate characteristic photon resulting from formation of the positron can also be detected) (Jean et al. 2003; Pethrick 1997). Because the electronic state of the positron and its environment in molecular media affect the annihilation process, PAS can provide information about the electron density and electron momentum of the annihilation site (Schrader and Jean 1988; Jean et al. 2003; Pethrick 1997; Hill et al. 2005; Tao 1972; Eldrup et al. 1981).

PAS is performed by irradiating a sample with positrons. Typically, the positron source for PAS is ^{22}Na (often prepared as a salt, such as $^{22}\text{NaCl}$) (Jean et al. 2003; Pethrick 1997). Other positron-emitting isotopes or beam-line sources, however, can be used to perform PAS (Jean et al. 2003; Rowe et al. 2009). One benefit of a beam-line source as opposed to an isotope source, such as ^{22}Na , is the ability to control the energy of the incident positron, which in turn, determines the positron's depth of penetration into the sample (Jean et al. 2003; Rowe et al. 2009). Therefore, PAS can be used to probe material properties as a function of depth from the surface (typically ranging from a few nanometers to several micrometers) when an appropriate beam-line source is available (Jean et al. 2003; Rowe et al. 2009).

Three techniques, positron annihilation lifetime spectroscopy (PALS), Doppler broadening

spectroscopy (DBS), and angular correlation of annihilation radiation (ACAR), are commonly used to perform PAS although other specialized techniques exist (Jean et al. 2003; Pethrick 1997). While DBS and ACAR provide information about positron annihilation mechanisms, PALS can provide information about the molecular-scale structure of molecular media (Pethrick 1997). As a result, PALS is often used to characterize molecular-scale voids (i.e., free volume) in membranes (Pethrick 1997; Hill et al. 2005; Rowe et al. 2009; Yampol'skii et al. 2006; Park et al. 2007; Ju et al. 2010; Xie et al. 2011; Tung et al. 2009; Zhang et al. 2012).

Positron Annihilation Technique

► Positron Annihilation Spectroscopy

Premix Membrane Emulsification

Goran T. Vladislavjević and Richard G. Holdich
Department of Chemical Engineering,
Loughborough University, Loughborough,
Leicestershire, UK

Premix membrane emulsification (PME) is a homogenization process based on passing

coarsely emulsified mixture of two immiscible liquids (pre-emulsion) through a microporous membrane (Suzuki et al. 1996) or porous bed of particles (Yasuda et al. 2010). In conventional PME (Fig. 1a), the dispersed phase does not wet the membrane surface ($\theta > 90^\circ$), and thus, hydrophilic and hydrophobic membranes are needed to manufacture oil-in-water (O/W) and water-in-oil (W/O) emulsion, respectively. If the pressure difference is lower than the capillary pressure in a pore (Fig. 1c), the droplets are retained by the membrane, which leads to emulsion separation rather than homogenization (Koltuniewicz et al. 1995).

If the membrane surface is wetted by the dispersed phase of the original emulsion ($\theta < 90^\circ$) and suitable surfactants are present in both liquid phases, a phase inversion may occur during homogenization (Fig. 1b), leading to the formation of W/O emulsion from an O/W premix or vice versa (Suzuki et al. 1999). The main advantage of PME with phase inversion is that a fine emulsion with high disperse phase concentration (over 80 vol.%) can be produced from a low-concentration premix. Using a membrane wetted by the middle phase of the multiple emulsion, W/O/W and O/W/O emulsion can be inverted into a W/O or O/W emulsion, respectively. In the case of inversion of W/O/W emulsion (Fig. 2), a lamellar structure is formed inside the pores consisting of surfactant bilayers

Premix Membrane Emulsification, Fig. 1 Pressure-driven membrane processes with oil-in-water pre-emulsion: (a) PME without phase inversion ($\Delta P > P_{cap}$, $\theta > 90^\circ$) (Suzuki et al. 1996). (b) PME with phase inversion

($\Delta P > P_{cap}$, $\theta < 90^\circ$) (Suzuki et al. 1999). (c) Phase separation ($\Delta P < P_{cap}$, $\theta > 90^\circ$) (Koltuniewicz et al. 1995). θ is the contact angle at which a dispersed-phase/continuous-phase interface meets the membrane surface

Premix Membrane Emulsification,

Fig. 2 Phase inversion of W/O/W emulsion into W/O emulsion using hydrophobic polycarbonate membrane. The original W/O/W emulsion consisted of liquid paraffin (middle phase), Span 80 (a hydrophobic surfactant), and Tween 20 (a hydrophilic surfactant), and a pore size was 3 or 8 μm (Hino et al. 2000)

Premix Membrane Emulsification, Fig. 3 PME using SPG membrane. The droplet size in the product emulsion was 9 μm and the membrane pore size was 10.7 μm (Vladislavljević et al. 2004)

separated by aqueous films. The aqueous films are ruptured at the pore outlets forming reversed micelles stabilized by mixed surfactants. This W/O emulsion can be redispersed into an aqueous surfactant solution to form a redispersed W/O/W emulsion containing more uniform internal droplets than the original W/O/W emulsion (Hino et al. 2000).

In order to achieve additional droplet size reduction and improve droplet size uniformity, emulsion can repeatedly be passed through the same membrane (Vladislavljević et al. 2004). Repeated membrane homogenization was originally developed for homogenization of large lipid vesicles using track-etch polycarbonate filters

(Olson et al. 1979). The advantages of premix over direct membrane emulsification are in smaller droplet sizes and higher droplet throughputs that can be achieved for the given pore size but at the expense of lower degree of monodispersity.

The droplet size in premix ME is determined by the membrane pore size, transmembrane flux, physical properties of the dispersed and continuous phase and emulsion formulation. Small droplet size in the product emulsion is favored by small membrane pore sizes, high transmembrane fluxes, and low interfacial tensions between the dispersed and continuous phase (Vladislavljević et al. 2004, 2006). The membranes used in PME are shirasu

porous glass (SPG) membrane (Fig. 3), polymeric microporous membranes (Hino et al. 2000), and microsieves (Nazir et al. 2011).

Pressure Decay Method

Alexey Volkov

A.V. Topchiev Institute of Petrochemical Synthesis Russian Academy of Sciences (TIPS RAS), Moscow, Russia

Pressure decay method is one of the standard experimental techniques for characterization of

membranes and membrane materials in terms of sorption, diffusivity, or permeance; this method has a rather high sensitivity (Ferrari et al. 2010; Mulder 1996). The principle of this method is based on estimation of amount of molecules sorbed or permeated through the membrane by monitoring of pressure decay in a chamber with a constant known volume, where the membrane is placed. The amount of gas or vapor sorbed by membrane material at a given pressure is determined by the difference between initial and actual pressures; for sorption experiments, the actual pressure is equilibrium one. Mass flow through the membrane is determined by monitoring of pressure decay in a chamber above the membrane with a constant volume (upstream side) in time. This technique is more commonly used for measurement of gas transport due to higher values of compression coefficients, and the schematic view of this experimental setup is shown in Fig. 1.

If the volume of upstream side V_{upstream} is already calibrated and known, the mole flow of the gas J through the membrane surface A over the time period Δt can be described as a function of pressure drop in the following equation with approximation of ideal gas law:

$$J(\text{mole}/\text{m}^2 \cdot h) = \frac{V_{\text{upstream}} \cdot \Delta p}{R \cdot T \cdot A \cdot \Delta t}$$

where R is universal gas constant and T is temperature. The method accuracy can be improved by avoiding any temperature fluctuations (e.g., in

Pressure Decay Method, Fig. 1 Schematic view of experimental setup to measure gas flow with pressure decay method: *PI* pressure indicator, V_1 calibrated volume of pipelines and fittings, V_2 calibrated vessel volume, V_3 calibrated vessel volume

case of gas expansion) during single measurement and proper selection of highly sensitive and accurate pressure indicator(s) for required pressure range.

The drawback of this method is that the driving force across the membrane is continuously changing during the single test since the upstream side is isolated from the gas supply. However, it is possible to consider a constant transmembrane pressure difference if the pressure drop for single test is negligible in comparison with absolute pressure in upstream side. On the other hand, such a pressure drop value should be sufficiently high enough to eliminate the undesired effect of temperature fluctuation and instrumental noise. From this end, the upstream side typically includes two or more vessels with different calibrated volumes (see Fig. 1), so the overall volume can be adjusted by connecting one of the vessels or its combination to the main line in order to measure the membranes with different permeance at the same experimental setup within desired experimental error.

Pressure decay method is also used as a rapid test for evaluation of the integrity of micro- and ultrafiltration membranes as well as membrane modules (AWWA Staff 2005). The upper side of wetted membrane is pressurized with a gas, which is below its bubble point pressure. Broken membrane or not proper sealing would be indicated by noticeable rate of pressure decay. Recently, a new self-calibration technique based on principles of pressure decay method was proposed for the express determination of liquid flux through flat-sheet membranes in a pressure range of 30–150 bar (Grekhov et al. 2012).

Pressure Retarded Osmosis (PRO) for Energy Generation

► Membranes for Blue Energy

Pressure-Retarded Osmosis

Chalida Klaysom and Ivo Vankelecom
Centre for Surface Chemistry and Catalysis,
KU Leuven, Leuven, Heverlee, Belgium

During the past decades, the world's constantly growing population and energy demand had brought the great challenges to thoroughly search for alternative energy resources. The mixing of fresh and saline water releases a tremendous energy that can potentially be used for power generation (Pattle 1954). In fact, there are huge resources where freshwater meets saline water that have not been explored. It has been estimated that this potential energy resource can generate 200 TWh/year of electric power, creating more than 10 % for the world energy demand (Achilli and Childress 2010). The energy released from the mixing of fresh- and saltwater can be captured by a membrane process, the so-called pressure-retarded osmosis (PRO).

PRO utilizes osmotic pressure (π) as the driving force for water to transport across a semipermeable membrane from a water source with lower salt concentration (low π) to a source with higher salt concentration (high π). The flow of water from the dilute source increases the volumetric flow at the concentrate side, and this flow can be used for driving a turbine to generate electricity (see Fig. 1).

Pressure-Retarded Osmosis, Fig. 1 Schematic diagram of (a) the first osmotic salination energy converter, proposed by Norman in 1974 (Norman 1974), and

(b) the first prototype PRO, designed and operated by Statkraft (Oslo, Norway) (Skilhagen et al. 2008)

There are three osmotic pressure-related membrane processes: reverse osmosis (RO), forward osmosis (FO), and PRO. Regarding applied hydraulic pressure (P), the required pressure to retain osmotic equilibrium, PRO can be viewed as the transition process from FO to RO as shown in Fig. 2.

RO membranes require a mechanical strength that can withstand the high pressure applied, while FO and PRO operate at much lower pressures, thus no special strength is strictly required. Typical RO membrane is thus designed to have a thin selective layer on top of thick support layer. The membrane performance and solute retention

Pressure-Retarded Osmosis, Fig. 2 (a) Illustration of the magnitude of the operating pressure and water flux of a membrane in the ideal case and direction of water and salt flux for (b) RO, (c) PRO, and (d) FO process

are determined by the top-skin layer. The support only provides the mechanical strength to the RO membranes and the liquid flows through it under the influence of a pressure gradient. On the other hand, for FO and PRO, the physical and chemical nature of support layers (e.g., porosity, tortuosity, and hydrophilicity) play an equally important role as the skin layer. The presence of unwetted pores or gas trapped inside the pores of the support in FO or PRO can cause internal concentration polarization (ICP) and dramatic flux reductions. Moreover, membranes suitable for FO and PRO are required to possess high salt rejection to prevent reverse salt passages and ICP and to be thin, highly porous, and hydrophilic in nature to favor high water fluxes and good transport of leakage salts. Additional mechanical strength (just enough to resist the installed operating pressure) is required for PRO.

The ideal water permeation rate across the membrane is a linear function of both osmotic pressure difference and the applied hydraulic pressure:

$$J_w = A(\Delta\pi - \Delta P)$$

where J_w is water flux and A is the water permeability constant. The power generated by a PRO system is expressed by

$$W = J_w \Delta P = A(\Delta\pi - \Delta P) \Delta P$$

It is clear that the power generated by PRO is a parabolic function of in which the maximum

value is estimated to be at $\Delta P = \Delta\pi/2$. Thus, the maximum power generated from PRO ($W_{max} = A\Delta\pi^2/4$) is proportional to the water permeability constant and the square of the osmotic pressure difference.

Principal Component Analysis (PCA)

René Ruby-Figueroa

Institute on Membrane Technology, National Research Council of Italy, ITM–CNR, Rende, Italy

PCA can be considered in many ways as the basis for multivariate analysis. It is probably the most widespread multivariate statistical technique used

in chemometrics. Perhaps the most famous early paper was by Pearson in 1901. However, the fundamental ideas are based on approaches well known to physicists and mathematicians for much longer, namely, those of eigen-analysis. In fact, some school mathematic syllabuses teach ideas about matrices which are relevant to modern chemistry. It is generally accepted that the revolution in the use of multivariate methods took place in psychometrics in the 1930s and 1940s of which Hotelling's paper is regarded as a classic. Natural scientists of all disciplines, from biologists, geologists, and chemists, have caught on to these approaches over the past few decades. Within the chemical community, the first major applications of PCA were reported in the 1970s and form the foundation of many modern chemometric methods (Wold 1987).

PCA can be described as a way of identifying patterns in data and expressing the data in such a way as to highlight their similarities and differences. PCA is a powerful tool to analyze patterns in data with high dimension. The main advantage of PCA is the possibility to compress the data: it means reducing the number of dimensions without loss of information. This approach has been recognized as a useful technique in data reduction, modeling, outlier detection, variable selection, classification, and prediction as well (Brereton 2003).

PCA provides an approximation of a data matrix $\mathbf{X}$, in terms of the product of two small matrices called $\mathbf{T}$ and $\mathbf{P}$ as reported in the following:

$$\mathbf{X} \approx \hat{\mathbf{C}} \cdot \hat{\mathbf{S}} = \mathbf{T} \cdot \mathbf{P}$$

where $\mathbf{T}$ is the scores, and ideally has the same dimensions as $\mathbf{C}$, and $\mathbf{P}$ the loadings ideally having the same dimensions as $\mathbf{S}$ (Brereton 2003). Each scores' matrix consists of a series of column vectors and each loadings matrix a series of row vectors, the number of such vectors equaling the rank of the original data matrix.

The mentioned matrix $\mathbf{X}$ has an order $n \times k$, in which n represents the experimental rows (also called objects) and k which corresponds to the

factors comprising the measurements made on the objects (Wold 1987).

The reduction of the dimension is performed by linear combination, named principal components (PCs). The first principal component covers as much of the variation in the data as possible. The second principal component is orthogonal to the first and covers as much of the remaining variation as possible and so on. The numbers of PCs are less than or equal to the number of original variables. The quantity of PCs is determined by using the eigenvalue.

It is easy to convert the PCs from number into graph by using statistical data and modern computers. As a matter of fact, it is common to think PCs geometrically as much as numerically, and often PCs are treated as much as objects in an imaginary space than mathematical entities. By using commercial software, it is possible to obtain a large number of graphs rapidly. Score plots and loading plots are the main way to visualize the PCs, helping to appreciate interrelationships between different variables as well as detect and interpret sample patterns, clusters, similarities, or differences (Brereton 2003).

Applications of this approach are immersed in different fields such as neuroscience, image processing, authentication, and differentiation of wines with different geographical origin (Saavedra et al. 2011), as well as for the identification of adulterate products. Applications of this approach in membrane processes have been reported with successful results. Typical examples are related to the analysis of membrane bioreactor fouling behavior (Maere et al. 2012), the prediction of ternary gas permeation through synthesized PDMS membranes (Ghadimi et al. 2010), and the analysis of nanofiltration of single and mixed salt solutions (Hesampour et al. 2010). Despite the advantages of this approach, PCA applied for the analysis of membrane processes is still in its infancy.

Principle of Biocatalytic Membrane Reactors (BMR)

Lidietta Giorno and Rosalinda Mazzei
Institute on Membrane Technology, National
Research Council of Italy, ITM-CNR, Rende,
Italy

Synonyms

Biocatalytic membrane reactors; Biochemical membrane reactors; Biological membrane reactors

Biocatalytic membrane reactors are systems where the biocatalyst is loaded/immobilised to membrane and the bioconversion occurs at the membrane level, so that the membrane functions as support for the biocatalyst, contactor between reaction components, reactor and separation unit.

The most common type of biocatalyst used in biocatalytic membrane reactors is enzyme. Whilst some enzymes are not very specific, many will catalyse only one reaction involving only certain substrates. Enzyme specificity is thought to be a consequence of its elaborate three-dimensional conformation which allows formation of the “active site,” a hydrophobic cavity responsible

for the catalytic ability of the enzyme. Binding to create the substrate-enzyme complex is in general due to weak attractive forces. Although a little controversial, the notion of active sites and the enzyme-substrate complex are universally accepted and form the starting point for most theories of enzyme action.

The relative chemical equation is:

The mathematical expression of the kinetic behaviour of enzymes is commonly known as Michaelis-Menten equation:

$$V_0 = \frac{V_{\max}[S]}{K_M + [S]} \quad (2)$$

The Lineweaver-Burke equation is obtained by rearranging the M-M equation in linear form:

$$\left[\frac{1}{V_0} \right] = \frac{K_M}{V_{\max}} \left[\frac{1}{[S]} \right] + \frac{1}{V_{\max}} \quad (3)$$

By plotting $\frac{1}{V_0}$ versus $\frac{1}{[S]}$ data, a straight line is obtained, where the intercept to y axis is $1/V_{\max}$ and the slope is $K_m/V_{\max}$. From this graph, it is easy to estimate K_m and $V_{\max}$.

When the enzyme is immobilised in a matrix such as a polymeric membrane, the observed reaction rate depends upon the reagent transport and intrinsic catalytic activity of the enzyme. The Michaelis-Menten constant is often larger for an immobilised enzymatic system than for the corresponding homogeneous system.

The use of Lineweaver-Burk plots with immobilised enzymes to determine apparent values for $V_{\max}$ and K_m is very common. For a kinetically controlled reaction, a straight line is obtained. A linear extrapolation to the axes allows the apparent values of these parameters to be accurately determined.

In the presence of diffusional limitations, the Michaelis constant's apparent value obtained by extrapolation of the Lineweaver-Burk plot is usually larger than that for the soluble form. Under these conditions, the Michaelis-Menten equation

can no longer account for the overall kinetics. In general, the kinetic mechanism for an immobilised enzyme can be simply represented as follows:

where S_0 and P_0 are the concentrations next to the immobilised enzymes, whilst S_b and P_b are the concentrations in the bulk phase. The constant k_{ds} is related to the diffusion of substrate from the bulk to the enzyme, and k_{dp} is related to the diffusion of product from the immobilised enzyme to the bulk phase. In Fig. 1, the concentration gradients for substrate and product through

Principle of Biocatalytic Membrane Reactors (BMR),
Fig. 1 Concentration gradients through immobilised enzyme matrix

Principle of Biocatalytic Membrane Reactors (BMR),

Fig. 2 Reaction catalyzed by free and immobilised enzyme

porous supports containing immobilised catalysts are schematised. The gradients in regions A–B are due to diffusion in the outer diffusion liquid film. The gradients in regions B–C are due to the joint effects of diffusion and reaction.

For reactions monitored by measuring the increase of product in the bulk phase, the profile of product concentration as a function of time will present a time lag due to the diffusion of substrate from the bulk to the enzyme-loaded membrane and diffusion of product from the immobilised enzyme to the bulk phase (Fig. 2).

Depending on the place where the enzyme is immobilised, there are two main cases:

- Biocatalytic membrane reactors with enzyme immobilised on the membrane surface
- Biocatalytic membrane reactors with enzyme immobilised within the membrane porous matrix

Biocatalytic Membrane Reactors (BMR): Enzymes Immobilised on the Membrane Surface

In order to permit the catalytic action of immobilised enzyme, the substrate must diffuse from the bulk to the biocatalytic support, and the products must diffuse away into the bulk solution.

Principle of Biocatalytic Membrane Reactors (BMR), Fig. 3 Schematic representation of transport for catalyst immobilised on the surface of insoluble support

In this particular case, a stagnant film (or Nernst diffusion layer, thus called by biochemists) forms around the particle through which the substrate molecules must diffuse to reach the surface. Thus, the surface concentration is less than the bulk concentration; the reaction proceeds less rapidly than the bulk substrate concentration would suggest (Fig. 3).

The Michaelis-Menten equation shows that an increase of K_m also corresponds to a decreased reaction rate; therefore, the diffusional effect is not surprising. The flux of substrate from bulk to immobilised interfaces is given by $J_s = k_s(S - S_0)$.

where J_s is the flux (moles per unit time per unit area), S and S_0 are the substrate concentration in the bulk phase and at immobilised enzyme interface, and k_s is the mass transfer coefficient.

At steady state, at the interface, the mass transfer of substrate must be counterbalanced by the consumption rate of the substrate. Then, assuming

that Michaelis-Menten equation applies at systems immobilised on the surface,

$$k_s(S - S_0) = \frac{V_{\max}[S]}{K_M + [S]} \quad (5)$$

The following is a dimensionless variable:

$$Da = \frac{V_{\max}}{k_s S_0} \quad (6)$$

Known as the Damköhler number, it has an important physical meaning, being a ratio between the maximum reaction rate and maximum mass transfer rate.

When $Da \ll 1$, the maximum transfer rate is much larger than the maximum reaction rate, which means that the system works at low mass transfer resistance. This is the case known as reaction-limited regime. This means that the system is kinetically controlled and the equation

$$V_{kin} = \frac{V_{\max}[S]_b}{K_M + [S]_b} \quad (7)$$

can be assumed.

When $Da \gg 1$, the reaction rate is larger than the mass transfer, which means that the mass transfer resistance is large and it is the limiting process. This is the case known as diffusion-limited regime and $V_{diff} = k_s[S]_b$.

The Damköhler number can be interpreted as the ratio of the slope of V_{kin} to that of V_{diff} , evaluated by plotting V versus $[S]_b$. If the slope of V_{diff} ($= k_s$) is less than that of V_{kin} ($= V_{\max}/K_M$) at $S_b = 0$, then $Da [= (V_{\max}/K_M)/(k_s)] > 1$ and the reaction is diffusion controlled; whilst, in the opposite case, the reaction is kinetically controlled.

The influence of mass transfer on the overall reaction is usually represented using the effectiveness factor, η , defined as:

$$\eta = \frac{\text{Observed reaction rate}}{\text{Rate that would be observed in absence mass transfer resistance}} \quad (8)$$

Principle of Biocatalytic Membrane Reactors (BMR),

Fig. 4 Concentration profiles through catalytic porous matrix

When $\eta \leq 1$, it means that the mass transfer resistance is large and the effect is a reduction of the observed activity of the catalyst.

For Da approaching zero (very slow reaction relative to maximum mass transfer rate), η approaches 1. This means that for the reaction-limited regime, the observed reaction kinetics can be approximate to the intrinsic reaction kinetics.

Biocatalytic Membrane Reactors (BMR): Enzyme Immobilised Within the Porous Matrix

Immobilisation of enzymes has a significant influence on their kinetics. This can be due to both structural changes of the biocatalyst and changes in the microenvironment around the enzyme.

The activity of the immobilised enzyme is governed from the chemical-physical properties of the microenvironment instead of that one of the bulk phase. When enzymes are immobilised within the internal surface of porous supports (Fig. 4), calculation of the observed substrate conversion rate needs evaluation of the concentration profile of the substrate within the diffusion layer.

With respect to the biocatalytic system in which biocatalyst is immobilised on the surface support, in this case, the additional resistance to substrate diffusion given by the porous matrix must be considered.

The effective diffusion coefficient (D_{eff}) and the local rate of substrate conversion (V) differ conceptually from their counterpart in solution, and important quantitative difference can also arise.

Substrate porosity, tortuosity and restricted diffusion influence their value. Porosity, ϵ_p , is given by the ratio of “area of support/area of pores”; only part of the support is void and available for diffusive transport, while most part is occupied by solid. Tortuosity, ϵ , is a factor representing the fact that the pore network is complex and not straight, therefore, diffusion occurs changing direction continuously. The tortuosity factor is assumed to be in the range of 1.4 to 7. Pores can have very small diameter, similar to substrate molecular dimensions and lead to a situation of restricted diffusion (expressed as K_p/K_r , roughly estimated as $[1 - r_{substrate}/r_{pore}]^4$).

Taking into account these considerations, the effective diffusion coefficient can be written as:

$$D_{eff} = D_{S_0} \frac{\epsilon_p}{\tau} \frac{K_p}{K_r} \quad (9)$$

In the 1930s, Thiele, Damköhler and Zeldovitch studied the influence of *diffusion within porous catalysts* upon reaction kinetics. They considered the example of a planar membrane containing enzyme distributed uniformly throughout. The result of combining the steady-state diffusion

equation with the applicable kinetics rate expression, the Michaelis-Menten equation, is:

$$Deff \frac{d^2[S]}{dx^2} - \frac{V_{max}[S]}{K_m + [S]} = 0 \quad (10)$$

where D_{eff} is the effective diffusivity, $[S]$ is the substrate concentration, V_{max} is the maximum velocity of the reaction, and K_m is the Michaelis constant, which means that, at steady state, the substrate diffusion rate through the porous support containing enzyme is equal to the conversion rate.

The values V_{max} and K_m are those which characterise the kinetics expression for the microenvironment within the porous structure.

A useful parameter to evaluate if an immobilised reaction system is limited by kinetics or mass transport is the Thiele modulus, ϕ , given by:

$$\phi = L \left(\frac{V_{max}}{D_{eff} \cdot K_m} \right)^{1/2} \quad (11)$$

which has the physical meaning of a *reaction rate/diffusion rate*.

As a final remark, it should be noted that, as for the enzyme in solution, immobilised enzyme kinetics may differ from the single substrate irreversible Michaelis-Menten model. In the case where the intrinsic kinetics is inhibited by substrate, if the substrate at the external phase is higher than the substrate concentration giving the maximum reaction rate, it happens that the local reaction rate inside the support is larger than that at the external phase. In this specific situation, it is possible to observe an effectiveness factor higher than unity. Other frequent cases are heterogeneous systems, such as the substrate solubility limit and the liquid-liquid interface.

Mass transport in dialysis

Dialysis is carried out under isobaric conditions, and there is no temperature or electrical potential gradient. The principle of the process is depicted in Fig. 1 (Strathmann et al. 2006).

Principle of Dialysis,

Fig. 1 Schematic drawing illustrating the principle of dialysis with two neutral components of different size

The schematic drawing shows a liquid solution containing a solvent and molecular components of different molecular weight or size, referred to as feed solution separated by a membrane from the solvent referred to as dialysate or “stripping” solution. Due to the driving force of a concentration difference, the components will diffuse through the membrane from the feed solution to the dialysate. Their fluxes through the membrane and the separation are determined by the diffusion rate in the membrane matrix.

There are different forms of dialysis depending on the constituents of the feed solution and the structure of the membrane. The most simple form is the dialysis of neutral components, i.e., the components in the solution do not carry any electrical charge.

Dialysis Mass Transport of Components Carrying No Electric Charges

The mass flux in dialysis of a mixture, which contains neutral components, only can be expressed by the phenomenological equation, which can then be related to Fick’s law by several approximations.

For a membrane and a feed solution with uncharged components, the flux of a component at constant temperature and pressure is given by:

$$J_i = -L_i \frac{d\mu_i}{dz} = -L_i RT \frac{d \ln a_i}{dz} = -L_i RT d \ln C_i \gamma_i \quad (1)$$

Here J is the flux, L is a phenomenological coefficient, μ is the chemical potential, a is the activity, C is the concentration, γ is the activity coefficient, z is the directional coordinate perpendicular to the membrane, and the subscript i refers to a component.

Assuming that the activity coefficient is 1 and replacing the phenomenological coefficient by the diffusion coefficient leads to:

$$J_i = L_i \frac{RT}{C_i} \frac{dC_i}{dz} = D_i \frac{dC_i}{dz} \quad (2)$$

Equations 1 and 2 indicate that Fick’s law can describe the mass transport in dialysis with feed solutions containing neutral components adequately if there is no coupling of fluxes and if the activity coefficient of the components in the membrane is unity, which is the case in many practical applications.

Dialysis Mass Transport of Electrolytes in a Membrane Without Fixed Ions

If feed solutions with charged components, i.e., electrolyte solutions, are treated by dialysis, the electroneutrality requirement must be satisfied. For a system consisting of a membrane and solutions with various ions, the electroneutrality condition requires

$$\sum_a |z_a| C_a = \sum_c z_c C_c \quad (3)$$

Here z is the valence, C is the concentration, and the subscripts a and c refer to anion and cation, respectively.

If the membrane contains fixed ions, they must be included in the electroneutrality requirement. The fixed charges in a cation-exchange membrane are negative and in an anion-exchange membrane positive. If there is no electrical current, the conservation of the electrical charge requires that cations and anions will move in the same direction. Thus,

$$\sum_a |z_a| J_a = \sum_c z_c J_c \quad (4)$$

The concentration of the electrolyte, e.g., a single salt, is related to that of the ions by:

$$C_a = \alpha v_a C_s \text{ and } C_c = \alpha v_c C_s \quad (5)$$

Here α is the degree of dissociation of the electrolyte, v is a stoichiometric coefficient, and the subscript s refers to the electrolyte.

The stoichiometric coefficient relates the number of ions to that of the salt molecules. For a completely dissociated monovalent salt such as NaCl, α and v are 1. For a salt such as CaCl₂, v_a is 1 and v_c is 2.

In an electrolyte solution, the fluxes of the ions are the result of an electrochemical potential gradient driving force. The electrochemical potential of ions is related to that of the electrolyte by:

$$\tilde{\mu}_s = v_a \tilde{\mu}_a + v_c \tilde{\mu}_c \quad (6)$$

Here $\tilde{\mu}$ is the electrochemical potential.

Since in dialysis no external potential and no hydrostatic pressure difference is applied, the flux of the ions can be described as a function of the diffusion coefficient and the concentration gradient by Eq. 2 if the activity coefficients are assumed to be 1. However, the fluxes of the ions are related to each other by the electroneutrality requirement and the conservation of charges with the consequence that in diffusion of an electrolyte which consists of a cation and an anion with significantly different diffusivities, the faster moving ion will cause a minute charge imbalance and thus an electrical potential gradient. This potential gradient is referred to as diffusion potential, and although it might be very small, it will slow down the faster diffusing ion and speed up the slower ion so that both ions will diffuse with the same velocity.

The flux of the completely dissociated monovalent electrolyte is related to that of the ions by:

$$\begin{aligned} J_s = J_a = J_c &= -D_s \frac{dC_s}{dz} = -D_a |z_a| \frac{dC_a}{dz} \\ &= -D_c z_c \frac{dC_c}{dz} \end{aligned} \quad (7)$$

Here J is the flux, C is the concentration, D is the diffusion coefficient, z is the charge number of the ion, dz is the directional coordinate, and the subscripts s , a , and c refer to salt, anion, and cation, respectively.

Rearranging Eq. 6 under consideration of Eq. 5 gives the diffusion coefficient of the salt as a function of the diffusion coefficients of the cations and anions:

$$D_s = \frac{D_a D_c (|z_a| + z_c)}{D_a |z_a| + D_c z_c} \quad (8)$$

Combination of Eqs. 6 and 7 gives the salt and ion fluxes for a completely dissociated monovalent salt at constant temperature and pressure in an ideal solution, i.e., the activity coefficients are 1:

$$J_s = \frac{D_a D_c (|z_a| + z_c)}{D_a |z_a| + D_c z_c} \frac{dC_s}{dz} \quad (9)$$

Here J is the flux, C is the concentration, D is the diffusion coefficient, z is the charge number or the directional coordinate, and the subscripts s , a , and c refer to salt, anion, and cation, respectively.

Equation 9 describes the flux of an electrolyte as a function of the diffusion coefficients of the individual ions. This is the consequence of the electroneutrality requirement for the transport of ions which have different diffusivities because the faster moving ion will cause the buildup of a minute electrical potential gradient which will slow down the faster ion and speed up the slower ion so that at steady state both ions move with the same velocity. Therefore, an average diffusion coefficient for each ion can be defined to describe the fluxes of the different ions which are coupled by the conservation of charges and the electroneutrality condition. The average diffusion coefficient $\bar{D}$ is given by:

$$\bar{D}_c = \bar{D}_a = D_s = \left(\frac{D_a D_c |z_a| + z_c}{D_a |z_a| + z_c D_c} \right) \quad (10)$$

Equation 9 describes the transport of a single electrolyte under the driving force of a concentration or activity gradient through a membrane that does not carry any fixed charges. In this case, all ions of the electrolyte are transported in the same direction even if their diffusion coefficient is quite different. The situation, however, becomes more complex if a feed solution contains more than one

electrolyte and if the membrane carries fixed charges. In this case, certain ions might be transported against their concentration gradient.

Dialysis Mass Transport of Electrolytes in Ion-Exchange Membranes

The fluxes of ions through ion-exchange membranes in dialysis are even more complex and may result in transport of certain ions against their concentration gradient as illustrated in Fig. 2. Figure 2a shows countercurrent coupled transport of H^+ - and Na^+ -ions through a cation-exchange membrane. This process is referred to as Donnan dialysis. Figure 2b depicts co-current transport of H^+ -ions and Cl^- -ions through an anion-exchange membrane.

In Donnan dialysis with a strictly permselective ion-exchange membrane, the flux of the co-ion, i.e., in Fig. 2a the Cl^- -ions, is 0, and the fluxes of the counterions, i.e., the Na^+ - and H^+ -ions, are equal but move in opposite direction. Thus, there is no net transport of electrical charges across the membrane, i.e., there is no electrical current, and the conservation of charges is fulfilled. For a system illustrated in Fig. 2a, the transport of a counterion, i.e., the Na^+ -ion, is the result of a flux of another counterion, i.e., H^+ -ion, in opposite direction under the driving force of a concentration gradient. Since no co-ions, i.e.,

Principle of Dialysis,

Fig. 2 Schematic drawing illustrating the fluxes across an ion-exchange membrane which separates two electrolyte solutions of different concentrations containing HCl and NaCl: (a) shows the fluxes through a cation-exchange membrane and represents countercurrent coupled flux, i.e., Donnan dialysis, and (b) shows the fluxes through an anion-exchange membrane and represents co-current coupled transport, i.e., diffusion dialysis

Cl^- ion, can permeate the cation-exchange membrane, the flux of the H^+ -ions must be identical to that of the Na^+ -ions. The fluxes are given by:

$$J_{\text{H}^+} = -2 \left(\frac{L_{\text{H}^+} L_{\text{Na}^+}}{L_{\text{H}^+} + L_{\text{Na}^+}} \right) \frac{RT d \ln a_{\text{H}^+}}{dz} = J_{\text{Na}^+} \quad (11)$$

The transport of Na^+ -ions due to the H^+ -ion flux results in a buildup of an activity gradient of the Na^+ -ions which is causing a back transport. When the Na^+ -ion flux caused by the activity gradient is identical to that caused by the H^+ -ion flux, equilibrium is reached, and there will be no further ion transport through the membrane. This equilibrium, which is referred to as Donnan equilibrium, is given by:

$$d \ln a_{\text{H}^+} = d \ln a_{\text{Na}^+} \quad (12)$$

The Donnan equilibrium between two solutions with different Na^+ -ion and H^+ -ion concentrations separated by a permselective cation-exchange membrane is

$$\frac{a'_{\text{Na}^+}}{a''_{\text{Na}^+}} = \frac{a'_{\text{H}^+}}{a''_{\text{H}^+}} \quad (13)$$

The superscripts ' and '' refer to the two solutions separated by the membrane.

Donnan dialysis plays an important role in water softening, and Eq. 12 determines which minimum and maximum concentrations of a counterion can be achieved by a given flux of another counterion.

Co-current coupled transport is illustrated in Fig. 2b which shows a solution containing a mixture of a salt, i.e., NaCl , and an acid, i.e., HCl , separated by an anion-exchange membrane from a solution containing no salt. The Cl^- -ion concentration in the solution containing the salt and acid mixture is assumed to be much higher than in the solution containing the acid only. Due to a concentration gradient, the Cl^- -ions permeate the anion-exchange membrane toward the solution containing the acid only. Because of the electroneutrality requirement, an anion can permeate the membrane only when accompanied by a cation. The anion-exchange membrane, however, is impermeable to cations such as Na^+ -ions, but it is to some extent permeable to H^+ -ions because

protons are transported in an aqueous solution and also in highly swollen ion-exchange membranes by a different transport mechanism (Cussler 1971). The Cl^- -ion concentration gradient across the membrane acts as driving force for the transport of H^+ -ions which are transported against their concentration gradient. The minimum concentration of the acid in the salt solution and the maximum concentration in the acid that can be achieved are given when the activity gradients of the H^+ -ion and the Cl^- -ion across the membrane are identical. The co-current transport of an anion with a H^+ -ion is of practical importance for the recovery of acids from spent pickling solutions containing the acid in a mixture with salts.

Mass transport in electrodialysis

In electrodialysis cation-exchange membranes carrying fixed negative electric charges and anion-exchange membranes carrying positive fixed charges are placed in alternating series between two electrodes. The mass transport is the result of an electrochemical potential gradient across the membrane, i.e., a gradient in the chemical and electrical potential. An electrical potential driving force is acting on charged components only and in such a way that negatively charged components, i.e., the so-called anions, migrate in the direction toward the positively charged anode and the positively charged cations migrate toward the negatively charged cathode, i.e., cations and anions move in opposite directions.

To describe the mass transport of a salt in an aqueous solution through a membrane which is used as frame of reference, three independent fluxes must be considered, i.e., the flux of the cations, the flux of anions, and the flux of the solvent. The transport of ions is the result of an electrochemical potential difference and the transport of the solvent through the membrane a result of osmotic effects and a coupling with the fluxes of the ions. Under certain conditions the solvent flux can be significant and must be taken into account.

Ion-exchange membranes carry positive or negative electrical charges fixed to a solid matrix, and they are, therefore, permselective as far as the transport of ions is concerned, i.e., the cation-exchange membranes are preferentially permeable to cations and the anion-exchange membranes are preferentially permeable to anions (Strathmann et al. 2006).

The mass transport in electrodialysis can be described by a phenomenological equation giving the flux of the individual components by:

$$J_i = \sum_k L_{ik} \frac{d\tilde{\mu}_k}{dz} = \sum_k L_{ik} \left(RT \frac{d \ln a_k}{dz} + z_i F \frac{d\phi}{dz} \right) \quad (1)$$

Here, J is the flux, L is a phenomenological coefficient, $\tilde{\mu}$ is the electrochemical potential, a is the activity, z is the valence of ionic species, F is the Faraday constant, ϕ is the electrical potential, dz is the directional coordinate perpendicular to the

membrane, and the subscripts i and k refer to the components of the mixture. Assuming an ideal solution, i.e., the activity of a component is identical to its concentration and without kinetic coupling between individual components and expressing the phenomenological coefficient by the Fick's diffusion coefficient, Eq. 1 becomes identical with the Nernst-Planck flux equation which is given by:

$$J_i = -D_i \left(\frac{dC_i}{dz} + \frac{z_i F C_i}{RT} \frac{d\phi}{dz} \right) \quad (2)$$

Here D_i is the diffusion coefficient of the component i in reference with the membrane.

The first term in Eq. 2 $D_i \frac{dC_i}{dz}$ represents the diffusion and the second term $D_i \frac{z_i F C_i}{RT} \frac{d\phi}{dz}$ the migration.

Thus, the Nernst-Planck equation is an approximation of the more general phenomenological equation.

In ion-exchange membrane separation processes such as electrodialysis, the flux of the cations through the cation-exchange membrane and the flux of the anions through the anion-exchange membrane are interdependent because of the electroneutrality requirement in the solution between the membranes.

Electrical Current and Ion Fluxes

In electrodialysis it is assumed that the total current through the membrane is carried by ions only, thus is:

$$i = \frac{I}{A} = F \sum_i |z_i| J_i \quad (3)$$

Here i is the current density, I the current, A the membrane surface, F the Faraday constant, J the flux, and z the valence, and the subscript i refers to cations and anions.

The current density i can be related to the specific conductivity κ by:

$$i = \kappa \frac{d\phi}{dz} \quad (4)$$

Here κ is the specific conductivity, φ is the electrical potential, and z is the directional coordinate.

The specific conductivity κ can be expressed by the specific electrical resistance, the equivalent conductivity, the ion migration velocity, or the ion diffusivity:

$$\begin{aligned}\kappa &= \frac{1}{\rho} = \sum_i |z_i| C_i \lambda_i = F \sum_i |z_i| C_i u_i \\ &= F^2 \sum_i |z_i| C_i \frac{D_i}{RT}\end{aligned}\quad (5)$$

Here ρ is the specific resistance, C is the concentration, F is the Faraday constant, λ is the equivalent conductivity, u is the ion migration velocity, D is the ion diffusion coefficient, R is the gas constant, T is the absolute temperature, and the subscript i refers to anions and cations.

Introducing Eqs. 4 and 5 into Eq. 3 and rearranging lead to:

$$\begin{aligned}i &= F \sum_i |z_i| J_i \\ &= F^2 \sum_i z_i^2 \frac{C_i D_i}{RT} \left(\frac{RT}{z_i C_i F} \frac{dC_i}{dz} + \frac{d\varphi}{dz} \right)\end{aligned}\quad (6)$$

Here i is the current density, C is the concentration, F is the Faraday constant, φ is the electrical potential, z is the valence, D is the ion diffusivity, R is the gas constant, T is the absolute temperature, and the subscript i refers to anions and cations.

The term $\frac{RT}{z_i C_i F} \frac{dC_i}{dz}$ has the dimension of an electrical potential gradient and represents the concentration potential, which is established between two electrolyte solutions of different concentrations. In electrodialysis this potential is established between the concentrate and the diluate solution. It represents an electromotive force, which has to be overcome by the applied electrical potential.

The Transport Number and Membrane Permselectivity

In an electrolyte solution, the current is carried by both ions. However, cations and anions usually carry different portions of the overall current. In

ion-exchange membranes the current is carried preferentially by the counterions. The fraction of the current that is carried by a certain ion is expressed by the ion transport number, which is given by:

$$T_i = \frac{|z_i| J_i}{\sum_j |z_j| J_j} \quad (7)$$

Here T_i is the transport number of the component i , J_i is its flux, and z_i is its valence and the subscript j refers to all ions involved in the charge transport.

The transport number T_i indicates the fraction of the total current that is carried by the ion i ; the sum of the transport number of all ions in a solution is 1.

The membrane permselectivity is an important parameter for determining the performance of a membrane in a certain ion-exchange membrane separation process. It describes the degree to which a membrane passes an ion of one charge and retains an ion of the opposite charge. The permselectivity of cation- and anion-exchange membranes can be defined (Spiegler 1957) by the following relations:

$$\psi^{cm} = \frac{T_c^{cm} - T_c}{T_a} \quad (8)$$

and

$$\psi^{am} = \frac{T_a^{am} - T_a}{T_c} \quad (9)$$

Here ψ is the permselectivity of a membrane, T is the transport number, the superscripts cm and am refer to cation- and anion-exchange membranes, and the subscripts c and a refer to cation and anion, respectively.

The permselectivity of an ion-exchange membrane relates the transport of electric charges by a specific counterion to the total transport of electric charges through the membrane and the transport number of the ion in the solution. An ideal permselective cation-exchange membrane would transmit positively charged ions only, i.e., for a

transport number of a counterion in a cation-exchange membrane $T_c^{cm} = 1$ is the permselectivity $\Psi^{cm} = 1$. The permselectivity approaches zero when the transport number within the membrane is identical to that in the electrolyte solution, i.e., for $T_c^{cm} = T_c$ is $\Psi^{cm} = 0$. For the anion-exchange membrane holds the corresponding relation.

The transport number of a certain ion in the membrane is proportional to its concentration in the membrane, which again is a function of its concentration in the solutions in equilibrium with the membrane phase, due to the Donnan exclusion. The concentration of a co-ion in an ion-exchange membrane can be calculated from the Donnan equilibrium. For a monovalent salt and a dilute salt solution and assuming the activity coefficients of the salt in the membrane and the solution to be 1, the co-ion concentration is given to a first approximation by:

$${}^m C_{co} = \frac{{}^s C_s^2}{C_{fix}} \quad (10)$$

Here C is the concentration; the subscripts co , s , and fix refer to co-ion, salt, and fixed ion of the membrane; and the superscripts s and m refer to membrane and solution.

Equation 10 indicates that the co-ion concentration in the membrane is increasing with solution salt concentration and the membrane permselectivity will decrease correspondingly.

Membrane Counterion Permselectivity

The transport number of different counterions in the membrane can be quite different. The transport rate of ions is determined by their concentration and their mobility in the membrane. The concentration of the counterions is always close to the concentration of the fixed charges of the membrane. The mobility of the ions in the membrane depends mainly on the radius of the hydrated ions and the membrane structure. The mobility of different ions in an aqueous solution does not differ very much from others. An

exception is the H^+ and OH^- ions. Their mobility is about a factor 5–6 higher than that of other ions. The exceptionally high mobility of the H^+ ion can be explained by the transport mechanism of protons. Salt ions move with their hydrate shell through the solution. Protons interact with water dipoles and form hydronium ions. They are transported in the membrane mostly via a so-called tunnel mechanism. The transport mechanism of the proton is also the reason for the high permeability of anion-exchange membranes for protons while these membranes generally have a very low permeability for salt cations. The same mechanism as the one described here for the transport of protons also holds true for the transport of hydroxide ions, and thus the permeability of hydroxide ions in a cation-exchange membrane is much higher than that of other salt anions.

The permselectivity of an ion-exchange membrane for different salt counterions is determined by the concentration and the mobility of the different ions in the membrane. The concentration of the different counterions in the ion-exchange membrane is generally also different. A typical counterion-exchange sequence of a cation-exchange membrane containing SO_3^- group as fixed charge is:

A similar counterion-exchange sequence is obtained for anions in an anion-exchange membrane containing quaternary ammonium groups as fixed charges:

Water Transport in Electrodialysis

Water transport in electrodialysis from the diluate to the concentrate process stream can affect the process efficiency significantly. If a convective flux as a result of pressure differences between flow streams can be excluded, there are still two sources for the transport of water from the diluate to the concentrate solution. The first one is the

result of osmotic pressure differences between the two solutions, and the second is due to electroosmosis which results from the coupling of water to the ions being transported through the membrane due to the driving force of an electrical potential.

Each of the two fluxes may be dominant depending on the permselectivity of the ion-exchange membrane, the concentration gradient, and the current density. In a highly permselective membrane and moderate differences in the salt concentration in the two solutions separated by the membrane, the electroosmotic flux is dominating and generally much higher than the osmotic solvent flux. In electrodialysis the water flux due to electroosmosis can be expressed by a solvent transport number which gives the number of water molecules transported by one ion:

$$J_w = {}^mT_w \sum_i J_i \quad (11)$$

Here mT_w is the water transport number, J_w is the water flux, and J_i is the flux of ions through a given membrane.

The water transport number thus is:

$${}^mT_w = \frac{J_w}{\sum_i J_i} \quad (12)$$

The water transport number refers to the number of water molecules transferred by one ion through a given membrane. It depends on the membrane and on the electrolyte, i.e., on the size of the ions, their valence, and their concentration in the solution. In aqueous salt solutions and commercial ion-exchange membranes, the water transport number is in the order of 4–8, i.e., one mole of ions transports ca. 4–8 mol of water through a typical commercial ion-exchange membrane.

Introduction

The principle of gas separation is illustrated in Fig. 1, which shows two different gas mixtures separated by a membrane. The driving force for the gas to permeate the membrane is a pressure gradient.

In gas separation both porous and dense membranes are used as selective barriers (Pandey and Chauhan 2001; Favre 2010; Yampolskii and Freeman 2010). In porous membranes the transport of gases is based on the so-called Knudsen diffusion. And in dense solid materials the gas transport is based on a solution-diffusion mechanism. Both the Knudsen diffusion as well as the solution-diffusion transport can result in a selective transport of gases and thus in a separation of gases. However, the extent of the separation, i.e., the separation factor is much higher in a solution-diffusion transport than in Knudsen diffusion.

Gas Separation by Knudsen Diffusion

Knudsen diffusion can be considered as viscous flow in narrow pores, i.e., pores with a diameter that is smaller than the mean free path length of the diffusing gas molecules. The mean free path length is defined as the average distance a gas molecule travels before it will collide with another gas molecule. The mean free path length of a gas molecule depends on the nature of the gas, the temperature, and the pressure. It is given by (Atkins 1990):

$$\lambda = \frac{kT}{\pi d_{\text{gas}} p \sqrt{2}} \quad (1)$$

Here λ is the mean free path length of a gas molecule, k is the Boltzmann constant, d_{gas} is the

Principle of Gas Separation, Fig. 1 Schematic drawing illustrating the principle of gas separation

diameter of the gas molecule, and p is the hydrostatic pressure.

The difference between viscous flow and Knudsen diffusion is illustrated in Fig. 2.

The figure shows two membrane pores of different diameter with a number of gas molecules. In the pore with the larger diameter, the gas molecules have more interaction with each other than with the pore wall since the mean free path length of the molecules is much shorter than the pore diameter. In the pore with the smaller diameter, the gas molecules have more interactions with the pore wall than with each other. In the case of the larger pores, the energy loss during transportation is mainly due to the interaction of the molecule with each other. It is expressed in the viscosity of the solution. Therefore, the flux is referred to as viscous flow in which all molecules are transported with the same rate. In pores with the smaller diameter, the energy loss during the transport of the gas molecule is due to their interaction with the pore wall. The process is similar to diffusion in a homogeneous solid phase and is therefore referred to as Knudsen diffusion. Since molecules of different mole mass have different interaction energies when colliding with the pore wall they are transported with different rates. This can be utilized to separate gases which differ in their molecular weight. The mean free path length of gases at room temperature and atmospheric pressure is in the order of a couple of nanometers. This means that only membranes with a mean pore size below a couple of nanometers can separate gases due to a Knudsen diffusion mechanism. Since the free path length of a gas molecule is pressure and temperature dependent as Eq. 1 indicates,

Principle of Gas Separation,

Fig. 2 Schematic drawing illustrating viscous flow and Knudsen diffusion

membranes with larger pore diameters can be used when the process is carried out at higher temperature and low pressure.

The flux in Knudsen diffusion can be described by the following relation (Mason and Malinauskas 1983):

$$J_i = \frac{\pi n r^2 D_i^k \Delta p}{RT \tau \Delta z} \quad (2)$$

Here J is the flux through the membrane, n is the number of pores in the membrane, r is the pore radius, Δp is the pressure difference across the membrane, Δz is the thickness of the membrane, τ is the tortuosity factor, and D^k is the Knudsen diffusion coefficient.

The Knudsen diffusion coefficient is given by:

$$D_i^k = 0.66r \sqrt{\frac{8RT}{\pi M_w}} \quad (3)$$

Equation 3 shows that the Knudsen diffusion coefficient of a gas molecule is inversely proportional to the square root of its molecular weight. Thus, the separation of two gases based on Knudsen diffusion is given by the ratio of the square root of the molecular weights.

$$\alpha_{j,k} \propto \sqrt{\frac{M_k}{M_j}} \quad (4)$$

Because of the Knudsen diffusion transport mechanism, the selectivity that can be achieved with porous membranes is in general rather low when gases differ only marginally in their molecular mass. Nevertheless, porous membranes are used to separate U^{235}F_6 from U^{238}F_6 . Since the selectivity is only ca. 1.0043, hundreds of stages are required to obtain a significant separation.

Gas Transport by the Solution-Diffusion Mechanism in a Polymer Matrix

Significantly higher selectivity can be obtained in homogeneous polymer membranes, where the transport mechanism is based on the solution and diffusion of the various components within the membrane phase. The mass transport in a

Principle of Gas Separation, Fig. 3 Schematic diagram illustrating the three-step transport mechanism in solution-diffusion type membranes (μ is the chemical potential, X is the molar fraction, C is the concentration, p is the partial pressure; the subscript i refers to a component and the superscripts f , p , g , and m refer to feed, permeate, gas phase, and membrane)

so-called solution-diffusion membrane is illustrated in Fig. 3. It consists of three relevant steps:

- Sorption of the various components from a feed mixture according to their partition coefficient between the gas and polymer phase
- Diffusion of the individual components within the membrane phase according to their activity gradients
- Desorption of the components from the membrane in the permeate gas phase

If viscous flow is excluded, the driving force for the mass transport of gases in solution-diffusion type membranes is the activity gradient of the permeating components within the membrane phase which can be related to the difference between the chemical potentials of the component in the feed and the permeate.

The flux across the membrane can be described again by the phenomenological equation as a function of the gradient of the chemical potential of the permeating component:

$$J_i = -L_i \frac{d^m \mu_i}{dz} \quad (5)$$

Here J is the flux, L is a phenomenological coefficient relating the flux to the corresponding driving force, μ is the chemical potential, and z is the directional coordinate perpendicular to the membrane surface, the subscript i refers to a component, and the superscript m refers to the membrane.

The chemical potential in the membrane at the membrane surface is equal to the potential in the adjacent gas phase. The change of chemical potential of a component as function of pressure and composition is given by:

$$d\mu_i = \bar{V}_i dp + dRT \ln a_i \quad (6)$$

Here a is the activity, p is the hydrostatic pressure, and $\bar{V}$ is the partial molar volume.

Introducing Eq. 6 into Eq. 5 gives the flux of the component i in the membrane:

$$J_i = -L_i (dRT \ln^m a_i + {}^m \bar{V}_i dp) \quad (7)$$

Since in the membrane the pressure is constant, i.e., $dp = 0$ and since $d \ln a = \frac{da}{a}$ Eq. 5 can be written as:

$$J_i = -L_i RT \frac{d^m a_i}{{}^m a_i} \quad (8)$$

Integration of Eq. 8 across the membrane gives the flux as function of the activity of the component i in the membrane at the interface between the feed gas and the permeate gas:

$$J_i = -L_i \frac{RT}{{}^m \bar{a}_i} \frac{{}^m a_i^p - {}^m a_i^f}{\Delta z} \quad (9)$$

Here ${}^m \bar{a}_i$ is the average activity of the component i in the membrane, and the superscripts f and p refer to product side and feed side of the membrane.

Since at the interface between the membrane and the gas the chemical potentials of the component i in the membrane and the gas are equal, i.e.,

${}^m \mu_i = {}^g \mu_i$, the activity of the component i in the membrane at the interface can be expressed by its activity in the gas.

The chemical potential of the component i in the membrane and in the gas is obtained by integration of Eq. 6.

In the membrane the partial molar volume of the component can be considered as constant and equal to the molar volume of the condensed gas.

Thus is:

$${}^m \mu_i = \mu_i^o + RT \ln^m a_g + {}^m \bar{V}_i ({}^m p - p^o) \quad (10)$$

Here the superscript o refers to a standard state.

In the gas the partial molar volume is a function of the pressure and in accordance with the ideal gas law $\bar{V}_i$ must be replaced by $\frac{RT}{p}$.

The chemical potential in the gas is then given by:

$${}^g \mu_i = \mu_i^o + RT \ln^g a_g + RT \ln \frac{p}{p_i^o} = \mu_i^o + RT \ln \frac{{}^g a_i p}{p_i^o} \quad (11)$$

Since the chemical potentials in the membrane and the gas at the gas membrane interface are equal it is:

$$\begin{aligned} {}^g \mu_i = {}^m \mu_i &= RT \ln \frac{{}^g a_i p}{p_i^o} = RT \ln^m a_i + {}^m \bar{V}_i ({}^m p - p^o) \\ &= \frac{{}^g a_i p}{p_i^o} = {}^m a_i \exp \frac{{}^m \bar{V}_i ({}^m p - p^o)}{RT} \end{aligned} \quad (12)$$

Here p_i^o is the saturation pressure of the gas.

It can be shown that the exponential term in Eq. 12 even at high pressure is always close to 1. Therefore, the activity of the component i at the interface with the gas can be expressed by:

$${}^m a_i^f = \frac{{}^g a_i^f p^f}{p_i^o} \text{ and } {}^m a_i^p = \frac{{}^g a_i^p p^p}{p_i^o} \quad (13)$$

Here the superscripts f and p refer to feed and permeate side of the membrane.

The activity of the component i in the membrane and in the gas can be related to its concentration in the membrane and its molar fraction in the gas by:

$${}^m a_i = {}^m X_i {}^m \gamma_i \text{ and } {}^g a_i = \frac{X_i \varphi_i}{p_i^0} \quad (14)$$

Here X is the molar fraction, γ is the activity coefficient, φ is the fugacity coefficient, and the superscripts m , g , and o refer to the membrane, the gas phase, and the saturation pressure.

Introducing Eqs. 13 and 14 into Eq. 9 leads to:

$$J_i = -L_i \frac{RT}{m \bar{X}_i {}^m \bar{\gamma}_i p_i^0} \frac{X_i^p p^p \varphi_i^p - X_i^f p^f \varphi_i^f}{\Delta z} \quad (15)$$

Here L is a phenomenological coefficient, X is the molar fraction in the gas, p is the pressure, φ is the fugacity coefficient, and ${}^m \bar{X}_i$ and ${}^m \bar{\gamma}_i$ are the average molar fraction and the average activity coefficient of the component i in the membrane, Δz is the thickness of the membrane, and the superscripts p , f , and o refer to permeate, feed, and saturation pressure, the subscript i refers to a component.

Introducing the relation between the phenomenological coefficient and the diffusion coefficient, which is $L_i = \frac{D_i C_i}{RT}$, and the relation between the molar fraction and the concentration which is ${}^m C_i = X_i \frac{{}^m \rho}{M_i}$, and assuming to a first approximation that the fugacity coefficients in the feed and the permeate are the same, i.e., $\varphi_i^p = \varphi_i^f$ Eq. 15 becomes:

$$J_i = -D_i \frac{\varphi_i^m \rho}{m \bar{\gamma}_i p_i^0 M_i} \frac{X_i^p p^p - X_i^f p^f}{\Delta z} \quad (16)$$

Introducing a sorption coefficient which is given by: $k_i = \frac{\varphi_i^m \rho}{m \bar{\gamma}_i p_i^0 M_i}$ into Eq. 4 leads to:

$$J_i = -D_i k_i \frac{X_i^p p^p - X_i^f p^f}{\Delta z} \quad (17)$$

Here D is the diffusion coefficient in the membrane, k_i is the gas sorption coefficient of the

membrane, ρ is the density, and M is the molecular weight, and the subscript i refers to a component.

The product of diffusion and sorption coefficient is the membrane permeability given by $P_i = D_i k_i$. Introducing the permeability P_i into Eq. 17 gives the flux J_i of a component through the membrane as a function of its molar fractions in the feed and permeate X_i^f and X_i^p , its fugacity coefficient φ_i , its permeability in the membrane P_i , the membrane thickness Δz , and the pressures in the feed and permeate p^f and p^p .

$$J_i = -P_i \frac{X_i^p p^p - X_i^f p^f}{\Delta z} \quad (18)$$

In deriving Eq. 18 several assumptions have been made which are generally valid for permanent gases. However, the assumption that the diffusion and the solubility coefficient are independent of concentration and pressure is not valid for easily condensable vapors. In permeation of organic vapors, the diffusion coefficient may vary by several orders of magnitude with the concentration of the permeating component in the membrane.

For the relationship between the diffusion coefficient and the concentration of the diffusing component, different equations accounting for dual sorption or free volume and structural changes of the polymer are discussed in the literature. It should be pointed out that in gas and especially vapors permeation it is generally not possible to predict the mass transport behavior of various components in a mixture from single component measurements.

For a practical application the separation efficiency of the membrane is a crucial parameter. In gas permeation the separation efficiency of a membrane is expressed by its selectivity and/or its separation factor. The selectivity of a membrane for various components of a mixture is defined by the ratio of the permeability. For a binary mixture with the components k and j , the selectivity is:

$$S_{j,k}^P = \frac{P_j}{P_k} \quad (19)$$

Here, $S_{j,k}^p$ is the permeation selectivity of a membrane for the components j and k , and P_j and P_k are their permeability.

The permeation selectivity can be split into two terms, i.e., the selectivity due to different diffusion coefficients of the components of the gas mixture or due to their solubility in the membrane:

$$S_{j,k}^p = S_{j,k}^D S_{j,k}^k \quad (20)$$

Here $S_{j,k}^D$ and $S_{j,k}^k$ are the diffusivity and solubility selectivity of a membrane for the components j and k .

The selectivity is a useful parameter to characterize a membrane. For the design of a membrane plant, however, the separation factor is more useful. For a binary mixture the separation factor is defined by:

$$\alpha_{j,k} = \frac{X_j^p X_k^f}{X_j^f X_k^p} \quad (21)$$

Here α is the separation factor and X is the mole fraction, the subscripts k and j refer to the two components, and the superscripts f and p refer to the feed and the permeate.

The separation factor is defined to be always >1 . It is related to the membrane selectivity by:

$$\alpha_{j,k} = S_{j,k} \frac{\frac{X_j^p P^p}{P^f} - X_j^f}{\frac{X_k^p P^p}{P^f} - X_k^f} \frac{X_k^f}{X_j^f} \quad (22)$$

Here S is the selectivity for a binary mixture, p is the pressure, X is the molar fraction, and the superscripts f and p refer to the feed and the permeate, and the subscripts k and j refer to the components in the mixture. The separation factor is always smaller than the selectivity and when the pressure ratio of feed to permeate becomes infinitely high. Thus is:

$$\lim_{\frac{p^p}{p^f} \rightarrow 0} \alpha_{j,k} = S_{j,k} \quad (23)$$

In vapor separation α is normally a function of the feed concentration.

Membrane contactors are systems where porous membranes are used to carry out mass transfer between phases. In membrane contactors the membrane does not work as a selective barrier, and it does not control the transport between the two adjacent phases. It is used as a nonselective interface placed between two phases where its function is to keep the two phases separated and in contact at the same time.

The key factor of the process is the use of porous membranes ($2 \cdot 10^{-3}$ – $1 \mu\text{m}$ of pore size) with different surface tension with respect to the phase to be separated. For example,

microfiltration membranes interposed between polar fluid (liquid or gas) phases. The membrane pores are sufficiently small to ensure that capillary and interfacial forces prevent direct mixing of the phases (as long as a transmembrane pressure value lower than the breakthrough pressure is used). In addition, porous membranes provide a large contacting surface area between the two phases.

Membrane contactors can be used to separate two immiscible liquids (liquid/liquid contactors, e.g., membrane-based solvent extraction or pertraction) as well as two miscible liquids. In this last case, a vapor phase is allowed to pass through the membrane pores under a temperature gradient, and the process is usually known as "membrane distillation." Membrane contactors are also used to absorb a component from a gas mixture into a liquid (gas/liquid contactor) or to remove dissolved gases from liquids (liquid/gas contactors). For membrane contactors that separate a gas and a liquid phase, it is of crucial importance that the phases also do not mix and therefore it is necessary that the liquid does not enter the pores. The transmembrane pressure, pore size, surface tension between liquid and membrane interface controls this. The relationship between pressure and pore size is described by Laplace equation:

$$\Delta P = -\frac{2\gamma \cdot \cos \vartheta}{r} \quad (1)$$

The liquid will not wet the membrane pore if the contact angle is greater than 90° . Supercritical fluid contactors aim to achieve transfer of species from a liquid phase into a supercritical carbon dioxide or vice versa.

Membrane Contactors Used to Separate Two Liquid Immiscible Phases

These types of contactors are used in membrane-based solvent extraction operations and in general the transport occurs between an aqueous and an organic phase. One of the two immiscible phases wets the membrane and contacts the other phase at

the pore mouth on the opposite side of the membrane. A higher transmembrane pressure from the nonwetting phase side keeps the wetting phase within the membrane pores avoiding its dispersion into the other phase. Based on the type of membrane, wetting phase, and transport direction, the following cases can be distinguished:

- The membrane is hydrophobic, the organic phase wets the membrane and the transport occurs from the aqueous to the organic phase.
- The membrane is hydrophobic, the organic phase wets the membrane and the transport occurs from the organic to the aqueous phase.
- The membrane is hydrophilic, the aqueous phase wets the membrane and the transport occurs from the aqueous to the organic phase.
- The membrane is hydrophilic, the aqueous phase wets the membrane and the transport occurs from the organic to the aqueous phase.

The theory of mass transfer in different systems has been reported by several authors (Prasad and Sirkar 1992). Figure 1a shows the solute concentration profile in hydrophobic flat membranes with organic in the side A and water in the side B. The organic phase wets the membrane and the extraction is from aqueous to organic.

The mass transport can be described in terms of resistances in series. In membrane contactor, the overall resistance to mass transport is given by three resistances: aqueous phase/membrane/organic phase:

$$\frac{1}{K_{tot}} = \frac{1}{k_{aq}} + \frac{1}{k_{pore}} + \frac{1}{k_{org}} \quad (2)$$

where, K_{tot} is the overall mass transfer coefficient; k_{aq} , k_{pore} , and k_{org} are the mass transfer coefficients in the aqueous phase, in the membrane pore, and in the organic phase, respectively.

For the various cases, assumptions can be made for negligible resistances respect to others. If bulk and surface transport resistance are considered negligible, transport occurs by diffusion under a concentration gradient. The solute flux from the aqueous to the organic phase bulk can be described by the general expression:

Principle of Membrane Contactors, Fig. 1 Solute concentration profile in hydrophobic flat membranes. (a) transport from aqueous to organic phase; (b) transport from organic to aqueous phase

$$J_i = k_{iaq} (C_{iaq}^b - C_{iaq}^o) = k_{imo} (C_{iorg}^o - C_{iorg}^{ob}) \\ = k_{iorg} (C_{iorg}^{ob} - C_{iorg}^{ob}) \quad (3)$$

Considering the organic side:

$$J_i = K_o (C_{iorg}^* - C_{iorg}^{ob}) \quad (4)$$

where, K_o is the overall mass transfer coefficient, C_{iorg}^* is an hypothetical organic phase concentration of component “i” in equilibrium with the bulk aqueous phase concentration (C_{iaq}^{ob}); C_{iorg}^{ob} is the concentration of component I in the organic bulk phase. These two concentrations are also related by a solute distribution coefficient:

$$m_i = \frac{C_{iorg}^*}{C_{iaq}^b} = \frac{C_{iorg}^o}{C_{iaq}^o} = \frac{C_{iorg}^{ob}}{C_{iaq}^{ob}} \quad (5)$$

where, C_{iaq}^* is an hypothetical aqueous phase concentration in equilibrium with the bulk organic phase concentration.

From these equations, a relation between K_o and the individual mass transfer coefficients is obtained:

$$\frac{1}{K_o} = \frac{m_i}{k_{iaq}} + \frac{1}{k_{imorg}} + \frac{1}{k_{iorg}} \quad (6)$$

From the aqueous side:

$$J_i = K_{aq} (C_{iaq}^b - C_{iaq}^*) \quad (7)$$

and

$$\frac{1}{K_{aq}} = \frac{1}{k_{iaq}} + \frac{1}{m_i k_{imo}} + \frac{1}{m_i k_{iorg}} \quad (8)$$

The profile concentration for transport occurring from the organic to the aqueous phase through a hydrophobic flat membrane is reported in Fig. 1b and relative equations are modified according to the direction of transport.

The cases of hydrophilic membranes wetted by aqueous phase are reported in Fig. 2a, b.

In these operations one of the phases involved is always a liquid, whereas the other one can be liquid or gaseous. The processes that can be performed are gas absorption, liquid scrubbing, and liquid-liquid extraction. They can be then considered as alternative systems to conventional packed towers and extractors. In all cases, the difference of concentration promotes the mass

Principle of Membrane Contactors, Fig. 2 Solute concentration profile in hydrophilic flat membranes. (a) transport from aqueous to organic; (b) transport from organic to aqueous phase

transport. In gas absorption and liquid scrubbing, the second phase is a gas from/to which volatile species are transferred. The membrane used is usually hydrophobic: the liquid phase is blocked at the pore entrance and the pores are gas filled; this configuration reduces the mass resistance given by the membrane due the volatile nature of the species that move from one phase to the other (their diffusion in gas is higher than in liquid). When compared to the resistance at the liquid side, the membrane is in fact usually negligible.

In liquid-liquid extraction, the phases involved are aqueous and organic (nonmiscible) and the membrane, as discussed before, can be hydrophobic or hydrophilic. The choice is always related to the situation that minimizes the mass resistance: usually, the phase in which the solute has higher solubility fills the membrane pores.

Membrane Contactors Used to Separate Two Miscible Liquids: Membrane Distillation

In this configuration system, a porous hydrophobic membrane is in contact with aqueous solutions

having different temperature on the two sides of the membrane.

The high interfacial tension between the hydrophobic membrane surface and the aqueous phase prevents the mass transfer of the aqueous phase as a liquid phase and forms a vapor-liquid interface at the pore entrance. Then the volatile compounds evaporate and are transported by diffusion and/or convection through the pores to the other side of the membrane where they are condensed and removed into the aqueous phase at lower temperature.

When the permeable side (often pure water) is in direct contact with the membrane, the system is known as direct contact membrane distillation (DCMD). There are also cases where the condensing phase is separated by an air gap from the membrane (AGMD), vacuum (VMD) or a sweep gas is used (SGMD).

Considering the mass transport in membrane distillation, the electrical potential can be neglected as neutral membranes and solvents are used, therefore the transport occurs under a chemical potential:

$$\Delta\mu = \bar{V}_i \Delta p + RT \ln \frac{a_i''}{a_i'} \quad (9)$$

Where, $\bar{V}_i$ is the partial molar volume of a component i ; a_i is the activity, and Δp is the hydrostatic pressure gradient.

In membrane distillation, the hydrostatic pressure gradient across the membrane is negligible. The driving force of the process is the vapor pressure difference across the membrane. The vapor liquid equilibrium for nonideal mixtures is described by:

$$p_i = Py_i = p_i^0 a_i = p_i^0 \gamma_i x_i \quad (10)$$

where, p is the total pressure, x_i and y_i are the liquid and vapor mole fraction, respectively.

Mass transfer for membrane distillation can be described in terms of resistances in series upon transfer between the bulks of two phases contacting the membrane. The surface boundary layer resistances are generally negligible. The controlling step is represented by the diffusion across the membrane.

In a porous medium, if surface diffusion is assumed negligible, mass transfer can be affected by viscous resistance (resulting from the momentum transferred to the supported membrane), Knudsen diffusion resistance (due to collisions between diffusing molecules), or ordinary diffusion (due to collisions between molecules and membrane walls) (Drioli et al. 2000n). Predominance, coexistence, or transition between all of these different mechanisms is estimated by comparing the mean free path λ of diffusing molecules to the mean pore size of the membrane (Knudsen number). Kinetic theory of ideal gases calculates λ as:

$$\lambda = \frac{k_B T}{P \sqrt{2} \pi \sigma^2} \quad (11)$$

where, k_B is the Boltzmann constant ($1.380 \cdot 10^{-23} \text{ JK}^{-1}$), and σ is the collision diameter of the molecule ($\sigma = 2.7 \text{ \AA}$ for water).

For the binary mixture of water vapor in air, the free mean path $\lambda_{a/w}$ can be evaluated at the average membrane temperature $\bar{T}$, by

$$\lambda_{a/w} = \frac{k_B \bar{T}}{\pi \left(\frac{\sigma_w + \sigma_a}{2} \right)^2} \frac{1}{P \sqrt{1 + \left(\frac{m_w}{m_a} \right)}} \quad (12)$$

where, P is the total pressure, σ_a ($=3.7 \text{ \AA}$) and σ_w the collision diameters, and m_a and m_w the molecular weight for air and water, respectively.

In the continuum region, the free mean path of the gas is small if compared with the average membrane pore diameter, and molecule-molecule collisions predominate over molecule-wall collisions. Knudsen number, defined as the ratio of the free path of the gas to the pore diameter, is < 1 and the flux can be described by the Darcy's law. In the Knudsen region this situation is reversed: the mean free path of the gas is large with respect to the average membrane pore diameter ($Kn > 1$), molecule-wall collisions predominate over molecule-molecule collisions, and the mass transport can be described by Knudsen's law. In many practical cases, λ is comparable to the typical pore size of membranes used in membrane distillation and no simplifications can be made in modeling the mass transfer operation. Dusty gas model (DGM) is frequently used for describing gaseous molar fluxes through porous media; the most general form (neglecting surface diffusion) is expressed as:

$$\frac{J_i^D}{D_{ie}^k} + \sum_{j=i \neq i}^n \frac{p_j J_i^D - p_i J_j^D}{D_{ije}^0} = -\frac{1}{RT} \nabla p_i \quad (13)$$

$$J_i^v = -\frac{\varepsilon r^2 p_i}{8RT \tau \eta} \nabla P \quad (14)$$

$$D_{ie}^k = \frac{2\varepsilon r}{3\tau} \sqrt{\frac{8RT}{\pi M_i}} \quad (15)$$

$$D_{ije}^0 = \frac{\varepsilon}{\tau} P D_{ij}^0 \quad (16)$$

where, J^D is the diffusive flux, J^v the viscous flux, D^k the Knudsen diffusion coefficient, D^0 the ordinary diffusion coefficient, p the partial pressure, R the gas constant, T the temperature, P the total pressure, η the gas viscosity, r the membrane radius, ε the membrane porosity, and τ the membrane tortuosity. Subscript e indicates the "effective" diffusion coefficient, calculated by taking into account the structural parameters of the membrane as shown in Eqs. 13 and 14.

Although dusty gas model was derived for isothermal systems, it is successfully applied in membrane distillation working under relatively small thermal gradients by assuming an average value of temperature across the membrane.

The adoption of empirical correlations is in some cases preferred. The transmembrane flux can be written as a linear function of the vapor pressure difference across the membrane:

$$J = C\Delta p \quad (17)$$

where, C is the membrane distillation coefficient, and Δp the partial pressure gradient evaluated at the membrane surfaces. In Eq. 14, the membrane distillation coefficient C is a function of the membrane properties (pore size, thickness, porosity, and tortuosity), properties of the vapor transported across the membrane (molecular weight and diffusivity), and operative temperatures.

At steady state, the heat flux can be written as:

$$Q = H\tau(T_h - T_c) \quad (18)$$

Where, Q is the heat flux; T_h and T_c are the temperature of the hot and cold side, respectively; H is the membrane heat transfer coefficient; τ is the temperature polarization coefficient.

The temperature polarization coefficient is defined as:

$$\tau = \left(\frac{T_1 - T_0}{T_h - T_c} \right) \quad (19)$$

where, T_1 and T_0 are the temperatures at the membrane interface.

As an indirect contact membrane distillation, in osmotic distillation the two phases involved are always aqueous solutions and the membrane hydrophobic; the principle of transport through the membrane pores is also the same as in membrane distillation. The only difference is related to the driving force used to promote the evaporation flux that is now achieved by using at the distillate side a hypertonic salt solution: the difference in solute concentrations between the solution to be treated and the distillate side leads to a vapor pressure difference which causes the transport of

the water vapor molecules. This different way of carrying out the process allows to operate at ambient temperature, without the need to heat the solution to be concentrated, and can be very useful when is important to avoid any phenomenon of denaturation of the solution. Also in this case, the resistance offered by the membrane is negligible. The resistances at the liquid sides lead now to a profile of concentration (concentration polarization) that affects the driving force and reduces the performance of the system. A control and optimization of the fluid-dynamic allows to minimize this phenomenon. The transmembrane flux can be calculated by:

$$C_m = C_b \exp\left(-\frac{J}{k}\right) \quad (20)$$

Where, k is the solute transfer coefficient in the liquid phase, C_b and C_m are the concentration in the bulk and at the membrane level, respectively.

Principle of Membrane Emulsifier

Lidietta Giorno

Institute on Membrane Technology, National Research Council of Italy, ITM–CNR, Rende, Italy

Membrane emulsifier is used to prepare oil-in-water, water-in-oil, water-in-oil-in-water, etc. emulsions. In this type of system, the porous

Principle of Membrane Emulsifier, Fig. 1 Schematic of a membrane emulsifier apparatus

membrane is used to disperse, drop by drop, an immiscible phase (named disperse phase) into another phase (named continuous phase). The disperse phase is present as small droplets suspended in the continuous phase.

In membrane emulsification, droplets are formed at the pore mouth of a membrane by forcing the dispersed phase to permeate through the membrane and stripping the droplets from the pore into the continuous phase by action of the axial velocity, Fig. 1. The driving force is a difference of pressure between the two phases. An important aspect is that the membrane is not wetted by the dispersed phase and the choice of the membrane strongly depends on this fact. Therefore, to prepare oil-in-water emulsion a hydrophilic membrane is used, as the oil phase does not wet the hydrophilic membrane. Both liquid streams and the membrane itself offer the resistance to the mass transport.

The droplet size depends on the balance between (i) properties of components (viscosity, interfacial tension, densities); (ii) properties of membrane (pore size and shape, porosity, wall

contact angle, tortuosity); and (iii) process parameters (transmembrane pressure, pressure drop, permeate flow of dispersed phase, axial velocity (drug force) of continuous phase, temperature) (Schroder et al. 1998).

Stability and density of emulsions prepared by membranes are very good, but productivity might represent a limiting aspect for large-scale application. In other words, low permeation rate is in general associated with emulsions having narrow size and uniform distribution.

The theoretical description of a membrane emulsification mainly takes into account the permeation of the dispersion phase through the membrane pores and the detachment mechanism of the droplet (Williams et al. 1998; Josceline and Tragardh 2000; Abrahamse et al. 2001; De Luca et al. 2004).

The flux of the disperse phase through the porous membrane may be assumed to occur by convection and to follow Darcy's Law when considering pores of cylindrical geometry. The equation reduces to the Hagen-Poiseuille equation. In the case of one active pore, the dispersed flow rate can be obtained as

$$Q_d = \frac{\pi d_p^4}{128 \xi} \frac{\Delta P_{\text{eff}}}{\mu_d L} \quad (1)$$

where Q_d is the flow rate of the dispersed phase; d_p is the pore diameter; μ_d is the viscosity of the dispersed phase; ξ is the pore tortuosity; L is the membrane thickness.

The transmembrane pressure is defined as the difference of applied pressures between each side of the membrane and it consists of two parts: capillary pressure, ΔP_γ , due to the curvature of the interface and to the dynamic interfacial tension, and the effective transmembrane pressure

$$\Delta P_{\text{eff}} = \Delta P_{tm} - \Delta P[\gamma(t), d_d] \quad (2)$$

or the drag of the disperse phase inside the pore which determines Q_d .

The droplet at the pore tends to form a spherical shape, whose radius of curvature, $d_d/2$, is related to the height of the spherical droplet, h , and to the membrane pore radius $d_p/2$ by

$$\frac{d_d}{2} = \frac{(d_p/2)^2 + h^2}{2h} \quad (3)$$

When the height of the growing droplet equals the pore radius, the droplet size reaches its minimum, $d_d = d_p$. Accordingly, the capillary pressure calculated by Laplace equation takes a critical value offering the maximum resistance to the disperse phase flow.

Droplet formation at an individual pore involves droplet growth and droplet detachment (Schroder et al. 1998; Peng et al. 1998). The growth process ends when a balance among all mechanical torques acting on the droplet is reached. At the end of this stage the droplet is still connected to the pore through a neck. When the connection is interrupted the detachment is completed.

The main forces acting on a droplet to determine its growth and detachment have been identified and reported in the literature (Schroder et al. 1998; Peng et al. 1998; Wang et al. 2000):

$$F_D = k_x 3\pi \mu_c d_d v_c^\infty \approx \frac{3}{2} k_x \pi \tau_w d_d^2 \quad (4)$$

F_D is the drag force produced by the continuous phase flow; k_x the wall correction factor; v_c^∞ the undisturbed tangential velocity of the continuous phase at the droplet center; τ_w the wall shear stress. The relationships of the continuous phase velocity and τ_w are widely reported either for laminar or for turbulent flow (Wang et al. 2000).

The main forces that account in the droplet formation are

- The interfacial tension force,

$$F_\gamma = \pi d_p \gamma(t); \quad (5)$$

- The force due to the difference of pressure needed to overcome capillarity,

$$F_{sp} = \frac{\gamma(t)}{d_d} \pi d_p^2 \quad (6)$$

- The dynamic lift force,

$$F_{dl} = \frac{0.761 \tau_w^{1.5} \rho_c^{0.5}}{\mu_c} d_d^3 \quad (7)$$

Assuming that the shape of the droplet is approximately spherical, the droplet size can be estimated from the following equation:

$$F_D \frac{d_d}{2} = \left(\sum_i F_i \right) \frac{d_p}{2} \quad (8)$$

which provides a relationship between the membrane pore size and the droplet size at equilibrium.

Principle of Membrane Reactors

Lidietta Giorno

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Membrane reactors are systems where a chemical or biochemical conversion is combined with a membrane operation.

The two main areas of membrane reactors are identified by the type of catalyst used, traditional chemical catalysts, or catalysts of biological origin, which also dictates the operating conditions. Hence, membrane reactors (mainly inorganic) working at high temperature ($100 < T < 600\text{ }^{\circ}\text{C}$) or membrane bioreactors working at low temperature ($<100\text{ }^{\circ}\text{C}$) are known (Giorno and Drioli 2010; Marcano and Tsotsis 2004).

In both types of reactors the membrane works in two main ways. In one case, the membrane is catalytically inert, it does not participate in the reaction directly, and it simply acts as a barrier to reaction components allowing selective supply of substrate and separation of the product(s) or intermediate(s). This type of system is known by the general term “membrane reactor.” In the other type of reactor, besides the ability to separate and compartmentalize, the membrane is also “catalytic,” the membrane itself is formed of catalytic moieties (e.g., zeolites, palladium, etc.), or it contains the (bio)catalyst (e.g., enzyme-loaded

membranes, TiO_2 , etc.); the membrane participates directly to the reaction. This type of system is called “catalytic membrane reactor.”

Membrane science and chemical and biochemical engineering contribute to the development of these systems by designing compact and flexible apparatuses where a chemical reaction is combined to a separation step in order to increase conversion. In fact, the separation process allows to remove product(s) from the reaction site thus enhancing the yield, according to Le Chatelier’s principle, by shifting the chemical equilibrium toward the formation of product.

Reaction yield and selectivity may strongly depend on membrane characteristics. This is true for reactions catalyzed by inorganic catalysts and in particular for reactions catalyzed by biocatalysts (e.g., enzymes, cells, etc.). In fact, in this case, in addition to the effects of membrane selectivity on reaction (e.g., by removing products or poisoning components) the physical-chemical properties of membranes may influence the catalyst structure (and therefore the catalyst selectivity) itself.

The use of polymeric membranes is more common for biocatalytic reactors as these systems can work in mild conditions of temperature and pressure. Due to the capabilities of membrane processes and biocatalysts to work with high selectivity, and of not requiring additives, biocatalytic membrane reactors are particularly promising for processes in the food and beverage, biotechnological, biomedical, and pharmaceutical fields.

The development of membranes made of various inorganic materials enlarged the application to a wider range of temperature and pressure conditions. Inorganic membranes are stable at higher temperature and have good chemical and mechanical resistance.

The type of reactions investigated in this area include dehydrogenation, esterification, hydrogenation, and partial and total oxidation.

Traditionally, the membrane reactors were applied in equilibrium-limited reactions. Nowadays, new applications are growing; for example, in biocatalytic reactors, the membrane can be used to remove some intermediate or side product that might deactivate the biocatalyst. In some cases, the membrane does not need to be selective, but it

serves as a contacting reactive interface between the phases flowing on the two separate sides of the membrane.

The modeling of chemical and biochemical membrane reactors mainly depends on the function of the membrane; for example, if the membrane works as a separation unit independent from the reaction, then the reactor is modeled according to traditional systems (e.g., continuous stirred tank reactors, plug-flow reactor, etc.) combined to a membrane separation; if the membrane is catalytic, then the intrinsic kinetic and mass transport at the membrane level must be considered.

General concepts in reactor design can be applied to the membrane reactor too. In Fig. 1 is summarized the information needed for reactor development.

The building of models and their comparison with experimental data are useful and reasonable approaches to investigate and understand reactor performance.

Both kinetics and transport properties are needed.

Principle of Membrane Reactors, Fig. 1 Data needed for reactor design

The general procedure to formulate the mass balance is

- Choose the balance region so that the variables are constant or change little within the system and draw boundaries around the balance region.
- Identify the transport streams which flow across the system boundaries (e.g., convective in, convective out; diffusive in, diffusive out).
- Write the balance (e.g., rate of accumulation of mass of i = rate of i in by flow – rate of i out by flow + rate of production of i by reaction).
- Express each balance term by measurable variables in mathematical form. Pressure (P), volume (V), concentration (C), flow rate (F) are usually the measured variables (total mass = ρV ; mass of i = $C_i V$).
- Introduce other relationships and balances so that the number of equations equals the number of dependent variables.
- Express the total mass balance:

$$\frac{dVC}{dt} = (FC_i)_{\text{IN}} - (FC_i)_{\text{OUT}} + (r_i V)_{\text{system}} \quad (1)$$

The steady-state balance equation for a membrane reactor working in reaction-limited regime can be written as

$$FC_f - FC_p + v_r V = 0 \quad (2)$$

where C_f and C_p are the feed and permeate concentration, respectively, v_r the reaction rate, and V the reactor volume.

From this, the reaction rate can be derived:

Principle of Membrane Reactors, Table 1 Component balances for various tank reactor systems

Reactor type	Terms in equation	Final form
Batch reactor	Flow term = 0	Acc = Production
Fed batch or semi-cont. reactor	Flow term out = 0	Acc = In + Production
Steady state CSTR	Acc = 0	In – Out + Prod = 0
Component C_i does not react	Prod = 0	Acc = In – Out
Constant volume CSTR	Simplifies to $V(ds/dt) = F(S_0 - S_1) + r_s V$	Acc = In – Out + Prod

$$V_r = \frac{F(C_f - C_p)}{V} \quad (3)$$

Table 1 summarizes the component balances for various reactor systems.

The most relevant examples for biological and inorganic membrane reactor will be discussed in the following.

Mass transfer in microfiltration

Principle of Microfiltration,
Fig. 1 Schematic drawing illustrating the principle of microfiltration

Microfiltration is a physical separation process that uses porous membranes with an average pore size between 0.1 and 10 μm . It promotes the separation of particles and dissolved components from fluids by a sieving mechanism, based on size exclusion. The principle of microfiltration is depicted in Fig. 1. The membrane separating a feed solution from a permeate or filtrate has a symmetric or asymmetric porous structure.

The driving force for the mass transport across the membrane is a pressure gradient. Since only large particles with diameters in excess of ca. 0.1 μm are separated by the membrane, the diffusion of particles and the osmotic pressure difference between the feed and filtrate solution are negligibly low, and the mass flux through a microfiltration membrane is given to a first approximation by:

$$J_v = \sum_i J_i \bar{V}_i \cong L_v \frac{\Delta p}{\Delta z} \quad (1)$$

Here J_v is the volume flux across the membrane, the subscripts v and i refer to volume and components in the solution, $\bar{V}$ is the partial molar volume, p is the pressure, L_v is a phenomenological coefficient referring to hydrodynamic permeability of the membrane, Δp is the pressure difference between the feed and filtrate solution, and Δz is the thickness of the membrane.

The mass transport in microfiltration membranes takes place by viscous flow through the

pores. The solid membrane matrix can be considered as completely impermeable. Therefore, the hydrodynamic permeability can be expressed in terms of the membrane pore size and the porosity and the solution viscosity according to Hagen-Poiseuille's law, which is given by:

$$J_v = \frac{\varepsilon r^2}{8\eta\tau} \frac{\Delta p}{\Delta z} \quad (2)$$

Here J_v is the flux, ε is the membrane porosity, r is the pore radius, η is the viscosity, τ is the tortuosity factor, Δp is the pressure difference across the membrane, and Δz is the membrane thickness.

The porosity is defined as the ratio of the pores' surface area to the membrane surface area. The porosity is always $\varepsilon < 1$. The tortuosity factor is defined as the ratio of the actual pore length to the thickness of the membrane taking into account that the pore length in general is somewhat longer than the cross section of the membrane. Thus, it is always $\tau > 1$.

Pressure difference between feed and permeate (i.e., transmembrane pressure) in the range of 0.1 and 2 bar is usually applied. Permeability value $>1,000 \text{ L h}^{-1} \text{ m}^{-2} \text{ bar}^{-1}$ is usually obtained with microfiltration membranes.

Another parameter which is of interest for the practical application of microfiltration is the separation characteristic of a membrane, which is generally expressed by the retention or rejection and is given by:

$$R_i = \left(1 - \frac{C_i^p}{C_i^f} \right) \quad (3)$$

Here R is the rejection coefficient, C is the concentration, the subscript i refers to a given component in the feed and the permeate, and the superscripts f and p refer to the feed and permeate or filtrate solutions. R is always ≤ 1 and a function of the particle and the pore size and pore size distribution. $R = 0$ means complete permeation, and $R = 1$ means complete rejection.

To account for changes in retentate concentration with increasing of volume reduction factor

(when operating in concentration mode) or with increasing of treated volume (when operating at constant volume) as well as for changes in membrane properties due to fouling as a function of time, the rejection is also evaluated on the basis of concentration of retentate (C_i^R) instead of the initial feed solution:

$$R_i = \left(1 - \frac{C_i^p}{C_i^R} \right) \quad (4)$$

Compared with conventional concentration processes, microfiltration appears to be a good alternative for minimizing the adverse effects of heat. In general, filtration processes do not involve phase changes or high temperatures, thus favoring the maintenance of the sensory and nutritional characteristics of the product.

Microfiltration is used in a wide variety of industrial applications where particles of size $>0.1 \mu\text{m}$ have to be retained from the liquid (such as bacteria and suspended solid) (Fig. 2). The main industrial applications are cold sterilization of beverages and pharmaceutical products, clarification of fruit juice, wine, and beer, and wastewater treatment (Mulder 1996).

The materials which constitute the membranes used in microfiltration systems may be either organic (polymeric materials) or inorganic (ceramic, glassy, and metallic materials), depending upon the contaminants that are desired to be removed or the type of application. Module configurations include hollow fiber, tubular, flat sheet, spiral wound, rotating, and vibrating devices.

A basic microfiltration set-up comprises a feed tank, a pump to force liquid through the membrane, and two pressure gauges mounted before and after the membrane to read the corresponding hydrodynamic pressure drop across the membrane. Microfiltration membranes can generally operate in one of two configurations (Scott and Hughes 1996):

Cross-flow filtration (Fig. 3a): the feed streams flow tangential to a membrane surface, and as

MICROFILTRATION PROCESS

Principle of Microfiltration, Fig. 2 Microfiltration process characteristics

Principle of Microfiltration,

Fig. 3 Scheme of microfiltration membrane set-up. (a) Cross-flow configuration: 1 pump, 2 and 3 pressure gauges, 4 tubular membrane, 5 back-pressure valve; (b) dead-end configuration: 1 nitrogen gas vessel, 2 back-pressure valve, 3 pressure gauge, 4 flat sheet membrane, 5 purge valve

a result of the application of an appropriate driving force, a permeating species passes through the membrane. Solution that is directed to the membrane surface is called the feed. Solution that passes along the membrane surface and back to the feed reservoir is the retentate. This solution is usually pumped back to the feed reservoir and recirculated.

Solution that passes the membrane is the permeate.

Dead-end filtration (Fig. 3b): all the feed flows perpendicular to the membrane surface, and the retained particles accumulate on the surface forming a filter cake. The thickness of this cake therefore increases with time and is either cleaned or replaced.

Principle of Microfiltration, Table 1 Comparison of advantages and disadvantages of cross-flow and dead-end microfiltration

Dead-end filtration	Cross-flow filtration
Low capital cost	High capital cost
High operating costs – membrane must be replaced after each use, and disposal can be a problem	Modest operating costs – membranes have extended lifetimes if regularly cleaned
Operation is simple – no moving parts	Operation is complex – filters require regular cleaning
Best suited to dilute (low solid content) solutions. Membrane replacement costs increase with particle concentrations in the feed solution	Best suited to high solid content solutions. Costs are relatively independent of feed solution particle concentrations

The most important properties of cross-flow and dead-end microfiltration are summarized in Table 1 (Baker 2004).

During the membrane filtration process, permeate flux may decrease significantly and rapidly until a final steady state as a consequence of fouling and concentration polarization phenomena.

The approaches to minimize the effects of membrane fouling and concentration polarization include (Hilal et al. 2005):

Feed pretreatment by using physical and chemical processes: the physical process usually consists of prefiltration to remove any suspended particles that may plug the module or adhere to the surface membrane. Chemical process involves addition of flocculation-coagulation agents limiting the membrane fouling by aggregation of the colloid fraction.

Membrane modification by using coating and grafting techniques in order to minimize and/or eliminate adhesive fouling.

Optimization of operating parameters: flow manipulation is the main focus of changing the operating parameters by using different strategies such as inserts, turbulence promoters, increased flow rates, mixers, backflushing, backpulsing, backwashing, and air sparging.

Cleaning procedures: the method involves the use of cleaning agents (such as acids, bases, enzymes, surfactants, and disinfectants) able to affect fouling material present on a membrane surface by removing or changing the morphology of the foulants or altering the surface chemistry properties of the deposit.

Mass transfer in NF

Nanofiltration (NF) is very similar to ultrafiltration and to reverse osmosis. In all three processes,

a hydrostatic pressure is applied to transport a molecular mixture to the surface of a membrane. In general, the solvent and some low molecular weight solutes permeate the membrane while other components are retained. The main difference between nanofiltration and ultrafiltration is the pore size of the membrane and thus the molecular weight of the components that are retained by the membrane. Ultrafiltration membranes have pores with diameters in the range of 2–10 nm, and components are separated by a sieving mechanism according to their size. The molecular weight cut-off of ultrafiltration membranes is between 1000 and 10^6 Da. Nanofiltration membranes have pore sizes between 0.5 and 2 nm, which correspond to a molecular weight cut-off value of about 400–500 Da. Due to the smaller pores, the permeability of nanofiltration membranes is lower than that of ultrafiltration membranes. Furthermore, the osmotic pressure of the solutions treated by nanofiltration may have a significant osmotic pressure. Therefore, the applied pressure is in general about an order of magnitude higher than in ultrafiltration but lower than in reverse osmosis. The main difference between nanofiltration and reverse osmosis is the transport mode in the membrane. While in nanofiltration, it is assumed that all components permeate the membrane exclusively through geometrically well-defined pores; it is assumed that in reverse osmosis the different components permeate the membrane by diffusion through a more or less homogeneous polymer matrix, and the separation is due to the solubility and the diffusivity in the polymer matrix. But there is an additional difference between ultrafiltration or reverse osmosis membranes. While both ultrafiltration and reverse osmosis are neutral, nanofiltration membranes carry often positive or negative electrical charges. Therefore, the separation properties of nanofiltration membrane are determined in general by two distinct properties: (1) the pore size of the membranes, which corresponds to a molecular weight cut-off value of about 400 (± 100) Da and (2) the surface charge which can be positive or negative and affects the permeability of charged components such as salt ions. Due to the electric interactions between ions and the membrane

Principle of Nanofiltration (NF), Fig. 1 Schematic drawing illustrating the principle and the mass transport in nanofiltration (Strathmann et al. 2006)

surface charge, for example, nanofiltration membranes are capable of separating monovalent from multivalent ions.

A schematic illustration of the principle of nanofiltration is shown in Fig. 1.

To describe the mass transport in nanofiltration as function of a hydrostatic pressure driving force, the same basic relations as used in ultrafiltration can be applied.

The transport of the individual can be described by:

$$J_i = L_i \frac{d\mu_i}{dz} = L_i \frac{d}{dz} (\bar{V}_i p + RT \ln a_i) + L_v^m C_i \frac{dp}{dz} \quad (1)$$

The total volume flux through the membrane is given by sum of the molar flux of the individual components multiplied by their molar volume:

$$J_v = \sum_i J_i \bar{V}_i = \sum_i \bar{V}_i L_i \frac{d}{dz} (\bar{V}_i p + RT \ln^m a_i) + L_v \frac{dp}{dz} \quad (2)$$

Here, J_v is the total volume flux and J_i that of the individual components, L_i is a phenomenological coefficient referring to the diffusion of the permeating components within the membrane pores, L_v is the hydraulic permeability of the membrane,

referring to the viscous flow through the pores, $\bar{V}$ is the partial molar volume, and μ_i the chemical potential of a component i , p is the hydrostatic pressure, and z is a directional coordinate.

The first term in Eqs. 1 and 2 describes the diffusive fluxes of the different components in the pores of the membrane under the driving force of a chemical potential gradient, and the second term describes the viscous flow of the solution through the pore due to the applied pressure.

Expressing the phenomenological coefficient L_w by $L_w = \frac{D_w C_w}{RT}$ and integration of Eq. 2 over the pore length and expressing the water activity gradient in the pores by the osmotic pressure difference between the feed and the filtrate lead to:

$$\begin{aligned} J_v &\cong \frac{\bar{V}_w^2 L_w}{\Delta z} (\Delta p + \Delta \pi) + L_v \frac{\Delta p}{\Delta z} \\ &= \left(\frac{D_w \bar{V}_w}{RT} + L_v \right) \frac{\Delta p}{\Delta z} + \frac{D_w \bar{V}_w}{RT} \frac{\Delta \pi}{\Delta z} \end{aligned} \quad (3)$$

Here, $\Delta \pi$ and Δp are the osmotic and the hydrostatic pressure differences between the feed solution and permeate.

It can easily be shown that for nanofiltration membranes with pore sizes in the range of ca. 1 nm the term $\frac{D_w \bar{V}_w}{RT}$ is of the same order of magnitude or large than the L_v . Thus, unlike in ultrafiltration the effect of the osmotic pressure on the solvent flux cannot be neglected in nanofiltration. Therefore, solvent flux at a given hydrostatic pressure difference is a function of the feed and permeate concentration.

If it is assumed that the solutions treated in nanofiltration are relatively dilute and that to a first approximation the activities of the individual components can be replaced by their concentrations. Equation 1 can be expressed by:

$$\begin{aligned} J_i &= {}^m D_i \frac{d}{dz} \left(\frac{\bar{V}_i {}^m C_i}{RT} dp + d {}^m C_i \right) \\ &\quad + L_v {}^m C_i \frac{dp}{dz} \end{aligned} \quad (4)$$

Here, the phenomenological coefficient is expressed by the diffusion coefficient, i.e., ${}^m D_i = L_i \frac{RT}{{}^m C_i}$.

In ultrafiltration, the concentration of a dissolved component in the membrane is related to that in the feed and permeates by a partition coefficient. The same is true in nanofiltration. The concentration in the membrane is:

$${}^m C_i = k_i {}^s C_i \quad (5)$$

Here, k_i is the partition coefficient, ${}^m C_i$ and ${}^s C_i$ are the concentrations of a component in the membrane and in the solution, respectively.

However, if the membrane carries positive or negative electric charges at the surface, the partition coefficient for ionic components such as salt ions is not only determined by size exclusion but also by the so-called Donnan exclusion which postulates that ions carrying the same charge as the membrane, i.e., the so-called co-ions, will be excluded from the membrane. The Donnan exclusion is the result of the Donnan potential which is established between the surface of an ion-exchange membrane in equilibrium with an electrolyte solution and the electroneutrality requirement which postulated that on a macroscopic scale positive and negative charges must be compensated. The Donnan potential and Donnan exclusion is discussed in dedicated entries. The Donnan potential between an ion-exchange membrane and a dilute electrolyte solution is given to a first approximation by:

$$\varphi_{Don} = \sum_i \frac{1}{z_i F} \left[RT \ln \frac{{}^s C_i}{{}^m C_i} \right] \quad (6)$$

Here, φ_{Don} is the Donnan potential, ${}^s C_i$ and ${}^m C_i$ are concentration of an ion in the solution and the membrane, respectively.

The exclusion of the co-ions in a dilute solution of a single monovalent electrolyte is given to a first approximation by:

$${}^m C_{co} = \frac{{}^s C_s^2}{C_{fix}} \quad (7)$$

Here, ${}^m C_{co}$, ${}^s C_s$ and C_{fix} are the co-ion concentration in the membrane, the electrolyte concentration in the solution, and the fixed-ion concentration of the membrane.

In nanofiltration, the concentration of the co-ion in the membrane determines the transport of an electrolyte through the membrane because of the electroneutrality requirement, which postulates that on a macroscopic scale in any electrolyte mixture positive and negative charges, must be compensated. Since in nanofiltration there is no electrical current, the fluxes of positive and negative charges must be identical. Thus is:

$$\sum z_i C_i = 0 \text{ and } \sum z_i J_i = 0 \quad (8)$$

Here, C and J are the concentration and the flux in an electrolyte mixture, z is the charge number of the individual components, and the subscripted i refers to the different components in the electrolyte including the fixed ions of the membrane.

As a result of the Donnan exclusion, the partition coefficient for a component between a nanofiltration membrane carrying positive or negative fixed charges and an electrolyte solution depends on two parameters, one is the size exclusion and the other is the Donnan exclusion. It is:

$$k_i = k_{\text{size}} k_{\text{Don}} \quad (9)$$

Here, k_i is the partition coefficient, k_{size} is the contribution of the size exclusion, and k_{Don} the contribution of the Donnan exclusion.

The partition coefficient can be dominated by the size exclusion or the Donnan exclusion depending on the size of the component or the charge density of the membrane and the concentration of charged components in the feed solution. The total value of the partition coefficient is always $0 \leq k \leq 1$.

The Donnan potential between a nanofiltration membrane with fixed charges and the adjacent solution has an additional effect on its separation in nanofiltration. The Donnan potential for a given membrane is proportionally inverse to the concentration of the solution in contact with its surface. Since the concentrations are different at the feed and the permeate side of the nanofiltration membrane, an electrical potential difference across the membrane is established which affects the transport of charged components through the membrane, and an additional term must be introduced

in Eq. 4 to describe the transport of ions. The flux of individual components through a nanofiltration membrane containing fixed positive or negative charges is given by:

$$J_i = {}^m D_i \left[\left(\frac{\bar{V}_i k_{\text{size}} k_{\text{Don}} {}^s C_i}{RT} \frac{dp}{dz} + k_{\text{size}} k_{\text{Don}} \frac{d {}^s C_i}{dz} \right) + \frac{z_i F k_{\text{size}} k_{\text{Don}} {}^s C_i}{RT} \frac{d\varphi}{dz} \right] + L_v k_{\text{size}} k_{\text{Don}} {}^s C_i \frac{dp}{dz} \quad (10)$$

The consequence of the additional driving force of the Donnan potential difference between two solutions separated by a nanofiltration membrane is that components with the same electrical charge such as mono- and divalent cations or anions can be separated when their diffusivity in the membrane is different.

Equation $R_i = \left(1 - \frac{C_i^p}{C_i^f} \right)$ gives the rejection of a certain component in nanofiltration under given operating conditions of applied hydrostatic pressure and feed water composition. The rejection can be calculated from the membrane fluxes by:

$$R_i = 1 - \frac{C_i^p}{C_i^f} = 1 - \frac{J_i}{J_v C_i^f} \quad (11)$$

Here, R_i is rejection of a solute i , C_i^p and C_i^f are the concentration of a solute i in the product and the feed solution, respectively.

For a quantitative determination of the rejection of a certain charged component i , its flux J_i must be known. Therefore, Eq. 10 must be integrated. This, however, is rather difficult because the partition coefficient and the Donnan potential is a function of the feed and permeate electrolyte concentrations. The consequence of the Donnan exclusion and the Donnan potential is that salts can be separated effectively from solutions with neutral components of the same molecular size. The rejection of ions is decreasing with increasing feed solution concentration. In multicomponent electrolyte solutions, ions having different charge numbers and/or different sizes such as mono- and multivalent ions can also be effectively separated by nanofiltration.

Principle of Nanofiltration (NF), Fig. 2 Schematic drawing illustrating the rejection and the solute and solvent flux of an electrolyte through a nanofiltration membrane carrying positive or negative fixed charges (a) at constant

feed concentration as function of the applied hydrostatic pressure and (b) at constant hydrostatic pressure as function of the feed concentration

A quantitative determination of the rejection of nanofiltration membrane as a function of concentration and the applied hydrostatic pressure in multicomponent electrolyte solutions is rather difficult. However, a qualitative treatment and a rational interpretation of experimental results is possible on the basis of the above derived Equations. In Fig. 2, the rejection of a salt by a nanofiltration membrane carrying positive or negative fixed charges at the surface is shown schematically.

Figure 2a indicates that the nanofiltration of an electrolyte solution at constant feed concentration with a membrane carrying fixed surface charges the solvent flux increases linearly with the applied hydrostatic pressure as predicted by Eq. 3. The solute flux, however, increases only marginally with the increasing pressure as indicated by Eq. 10.

Therefore, the rejection will increase with the applied pressure according to a hyperbolic function and approaches its maximum value at infinitely high pressure. At constant pressure, the solvent flux will decrease more or less linearly with increasing feed concentration due to the increase of the osmotic pressure as indicated in Eq. 3. The solute flux increases exponentially with increasing concentration. Therefore, the rejection decreases exponentially with increasing concentration and will become 0 when the osmotic

pressure of the feed solution is equal to the applied hydrostatic pressure.

The qualitative description of the mass transport in nanofiltration based on Eqs. 3 and 10 is well in agreement with experimental results. The mass transport in nanofiltration membrane has also been discussed in the literature in various publications (Wang et al. 1995; Tsuru et al. 1991; Bowen and Mukhtar 1996; Shafer et al. 2005).

Mass transfer in PV

Pervaporation is a membrane process in which the permeation of certain components through a membrane from a liquid feed mixture into a vapor phase is combined with the evaporation of these components (Strathmann et al. 2006). The principle of the process is illustrated in Fig. 1.

The membranes and transport mechanism of a component through these membranes used in pervaporation are the same as in gas separation. The driving force for the transport is the chemical potential gradient of the permeating components in the membrane. The chemical potential gradient in the membrane can be related to the partial vapor pressures in the liquid and vapor phase. To establish a partial pressure difference of a component in the liquid and the vapor phase, generally, a vacuum is applied at the permeate side of the membrane. But differences in the partial pressure of a component can also be established by using a sweeping gas on the permeate side or by a

Principle of Pervaporation, Fig. 1 Schematic drawing illustrating the principle of pervaporation showing an asymmetric membrane with a dense solution-diffusion type barrier layer

temperature difference between the liquid feed and the vapor.

The mass transport in a pervaporation membrane can be described by the same mathematical relations as the gas transport with the exception that the chemical potential in the membrane on the feed side of the membrane is not expressed by the molar fraction, the hydrostatic pressure, and the fugacity coefficient but by the molar fraction and the activity coefficient in the liquid phase and the saturation pressure of the component.

Thus, the mass transport in pervaporation is given by:

$$J_i = -D_i k_i \frac{X_i^p p^p - X_i^l \gamma_i^l p_i^0}{\Delta z} \quad (1)$$

Here, D_i is the diffusion coefficient of the component i in the membrane, k_i is the sorption coefficient of the component i into the membrane matrix, X is the molar fraction, p is the pressure, γ is the activity coefficient, the subscripts j and k refer to components of the mixture, and the superscripts o , l , and p refer to saturation pressure, feed, and permeate, respectively.

Equation 1 describes the permeation flux of a component i as a function of the feed and permeate

mixture composition and its diffusivity and solubility in the membrane which can easily be determined by independent measurements. The practical application of Eq. 1, however, is rather limited since the diffusion coefficient as well as the distribution coefficient are not constant but depend strongly on the concentration of the permeating component in the membrane. This dependency must be determined experimentally and may be different for different membrane materials and vapors.

The product of diffusion and distribution coefficient is referred to as permeability coefficient, and the ratio of the permeability coefficients of two components determine the membrane selectivity for the two components.

$$D_i k_i = P_i \quad (2)$$

and

$$S_{j,k} = \frac{P_j}{P_k} \quad (3)$$

Here, P is the permeability of the membrane, S is the membrane selectivity, and j and k refer to the components of the mixture.

The separation factor in pervaporation of a two-component mixture is given by:

$$\alpha_{j,k} = \frac{X_j^p X_k^p}{X_j^l X_k^l} = S_{j,k} \frac{X_j^p \varphi_j^p - X_j^l \gamma_j^l p_j^0}{X_k^p \varphi_k^p - X_k^l \gamma_k^l p_k^0} \frac{X_k^l}{X_j^l} \quad (4)$$

Here, α is the separation factor, S is the membrane selectivity, X is the molar fraction, p is the pressure, γ is the activity coefficient, the subscripts j and k refer to components of the mixture, and the superscripts o , l , and p refer to saturation pressure, feed, and permeate, respectively.

In pervaporation, the partial pressure of the components on the permeate side is kept as low as possible by either using a sweeping gas or more commonly by applying a vacuum, i.e., $X_j^p p^p \ll X_j^l \gamma_j^l p_j^0$ and $X_k^p p^p \ll X_k^l \gamma_k^l p_k^0$. For a pervaporation experiment using a vacuum, the separation factor is to a first approximation:

$$\lim_{p^p \rightarrow 0} \alpha_{j,k} = S_{j,k} \frac{\gamma_j^l p_j^0}{\gamma_k^l p_k^0} \quad (5)$$

It should be noticed that the separation factor consists of two terms, the first term, i.e., $S_{j,k}$, represents the membrane selectivity, and the second term, $\frac{\gamma_j^l p_j^0}{\gamma_k^l p_k^0}$, the thermodynamic liquid/vapor equilibrium which represents the separation that would be achieved by distillation. In pervaporation, the membrane selectivity can increase or decrease the distillation selectivity and eventually push the overall separation factor into the opposite direction.

Mass transfer in Reverse Osmosis RO

Principle of Reverse Osmosis (RO), Fig. 1 Schematic drawing illustrating the principle of reverse osmosis

In reverse osmosis the driving force is also a hydrostatic pressure difference. The principle of the process is illustrated in Fig. 1, which shows a solution containing a low molecular weight component separated by a membrane from the solvent and a hydrostatic pressure difference applied across the membrane resulting in a flux of solvent from the solution into the pure solvent (Strathmann et al. 2006).

The membrane used in reverse osmosis has an asymmetric structure with a dense barrier layer at the side facing the feed solution. It is assumed that in this layer the individual components are transported by diffusion and that viscous flow through pores or pinholes can be neglected. For describing the transport in reverse osmosis membranes two approaches are described in the literature. One is the so-called solution-diffusion model which neglects kinetic coupling of different fluxes (Merten 1966). The second is based on the phenomenological equation of the thermodynamic of irreversible processes (Katchalsky and Curran 1967). This model does consider kinetic coupling between different fluxes. Both models describe the transport in reverse osmosis membranes quite accurately indicating that kinetic coupling is not of great importance in reverse osmosis.

Reverse Osmosis Mass Transport Described by the Solution-Diffusion Model

In the solution-diffusion model, the flux of different components through a membrane is assumed to be

by diffusion only and can be described by the product of its concentration and mobility in the membrane matrix and the chemical potential gradient of the component in the membrane. Furthermore, it is assumed that there is no kinetic coupling between fluxes, that the volume flux is approximately identical to the flux of the solvent, and that the solute flux due to the pressure gradient is negligibly small compared to the solute flux due to the activity gradient.

Thus, the flux of a component in the membrane can be described by:

$$J_i = L_i d\mu_i = L_i (\bar{V}_i dp + RT d\ln a_i) \\ = \frac{D_i^m C_i}{RT} (\bar{V}_i dp + RT d\ln a_i) \quad (1)$$

Here, J is the flux, L is phenomenological coefficient, μ is the chemical potential, p is the hydrostatic pressure, a is the activity, $\bar{V}$ is the partial molar volume, D is the diffusion coefficient, and $^m C_i$ is the concentration in the membrane; the subscript i refers to a component.

For the solvent, i.e., $i = w$ it is assumed that $J_v \cong J_w$ and $C_w \bar{V}_w = 1$. For the solute, i.e., $i = s$ it is assumed that: $d\mu_s \cong RT d\ln a_s$ and $\pi \cong \frac{RT \ln a_w}{\bar{V}_w}$. Here the subscripts v , w , and s refer to volume, solvent, and solute.

Integrating over the cross section of the membrane and expressing the activity of the solvent by the osmotic pressure and that of the solute by its concentration gives the volume flux to:

$$J_v = L_w \bar{V}_w^2 (\Delta p - \Delta \pi), \quad (2)$$

and the solute flux to:

$$J_s = D_s^m C_s d\ln^m C_s = D_s d^m C_s \quad (3)$$

The concentration of the different components in the membrane is proportional to the concentration in the outside solutions and it is given by:

$$^m C_i = k_i C_i \quad (4)$$

Here, k_i is the partition coefficient of the component i between the membrane and the adjacent solution, C_i and $^m C_i$ are the concentrations in the outside solution and in the membrane.

Introducing Eq. 4 into Eqs. 2 and 3 gives the volume flux, i.e., the filtration rate, and the flux of the solute as function of the applied hydrostatic pressure, the osmotic pressure, the diffusion coefficient of a component in the membrane, its concentration in the feed and permeate solution, and its partition coefficient between the membrane and the feed solution:

$$\begin{aligned} J_v &= \frac{k_w D_w C_w \bar{V}_w^2}{RT} (\Delta p - \Delta \pi) \\ &= \frac{k_w D_w \bar{V}_w}{RT} (\Delta p - \Delta \pi) \end{aligned} \quad (5)$$

and

$$J_s = k_s D_s (C_s^f - C_s^p) \quad (6)$$

Here, J_v is the volume flux, J_s is the solute flux, D is the diffusion coefficient, k is the partition coefficient of the components between the membrane and the adjacent solutions, C is the concentration, p the hydrostatic pressure, and π the osmotic pressure of the solutions, the subscripts s and w refer to solute and water, respectively, and the superscripts m , f , and p refer to the membrane, the feed, and the permeate. Furthermore is $V_w C_w = 1$.

To determine the rejection, the Eqs. 5 and 6 are introduced into Equation $R_i = \left(1 - \frac{C_i^p}{C_i^f}\right)$. Thus is:

$$\begin{aligned} R_s &= 1 - \frac{C_s^p}{C_s^f} = 1 - \frac{J_s}{J_v C_s^f} \\ &= 1 - \frac{k_s^m D_s (C_s^f - C_s^p) RT}{k_w^m D_w \bar{V}_w (\Delta p - \Delta \pi) C_s^f} \end{aligned} \quad (7)$$

Equation 7 shows that rejection of a component in reverse osmosis is not only a function of the membrane and feed solution properties it is also a function of the applied hydrostatic pressure. The rejection will increase with increasing applied hydrostatic pressure and approaches asymptotically a maximum value.

Reverse Osmosis Transport Described by the Phenomenological Equations

In deriving Eqs. 5, 6, and 7 on the solution diffusion model, a number of assumptions have been made including the neglecting of all kinetic coupling between transported components and any viscous flow. A more comprehensive treatment of the mass transport in reverse osmosis membranes, where kinetic coupling and convective flow are taken into account, is based on phenomenological equations applied to the laws of the thermodynamic of irreversible processes. In a reverse osmosis system, which consists of a membrane and a two component feed solution, i.e., a solvent and a solute, two independent fluxes will be obtained when the membrane is used as frame of reference. These fluxes can be described by:

$$J_i \sum_k L_{ik} X_k (i, k = 1, 2, 3 \dots, n) \quad (8)$$

Here, J is the flux of the different components, L is the phenomenological coefficient, and X is the driving force, the subscripts i and k refer to different components.

Assuming a system without viscous flow composed of a solute, a solvent, and a membrane as frame of reference there are two independent fluxes:

$$J_w = L_w d\mu_w + L_{ws} d\mu_s \quad (9)$$

and

$$J_s = L_{sw} d\mu_w + L_s d\mu_s \quad (10)$$

Here, J is the flux, μ is the chemical potential, L is the phenomenological coefficient, the subscripts w and s refer to the solvent which is assumed to be water and the solute which is assumed to be salt, the subscripts ws and sw refer to the coupling between the fluxes of water and salt and salt and water.

The diagonal coefficients L_w and L_s are always positive while coupling coefficients L_{sw} and L_{ws} can be positive or negative as can be seen from the dissipation function which describes the entropy production in a process. The total number of coefficient in the phenomenological equations is

reduced by the Onsager relation, which postulates that the coupling coefficients L_{sw} and L_{ws} are identical (Onsager 1931a, b). However, Eqs. 9 and 10 are not very useful to describe the transport properties of a reverse osmosis membrane because the coupling coefficients are difficult to determine in an independent measurement and generally in reverse osmosis the total filtration rate, i.e., the volume flux is of interest. However, the coupling coefficient can be converted to more easily measurable constants when the phenomenological equations are slightly modified by introducing the volume flux and a diffusive flux (Kedem and Katchalsky 1961).

The dissipation function for the Eqs. 9 and 10 is given by:

$$\begin{aligned}\Psi &= J_w d\mu_w + J_s d\mu_s \\ &= J_w d(\bar{V}_w p + RT \ln a_w) \\ &\quad + J_s d(\bar{V}_s p + RT \ln a_s)\end{aligned}\quad (11)$$

Here, ψ is the dissipation function, J is the flux, a , μ , and $\bar{V}$ are the activity, the chemical potential, and the partial molar volume, and p is the hydrostatic pressure, the subscripts w and s refer to solvent and solute.

Assuming a linear relation for the chemical potential gradients and introducing the osmotic pressure for the activities of the water and solute integration of Eq. 11 lead to:

$$\begin{aligned}\Psi &= (J_w \bar{V}_w + J_s \bar{V}_s) \Delta p \\ &\quad + \left(\frac{J_s}{C_s} - J_w \bar{V}_w \right) \Delta \pi \\ &= J_v \Delta p + J_D \Delta \pi\end{aligned}\quad (12)$$

Introducing a volume and a diffusion flux given by:

$$J_v = J_w \bar{V}_w + J_s \bar{V}_s \quad (13)$$

and

$$J_D = \frac{J_s}{C_s} - \bar{V}_w J_w \quad (14)$$

into the dissipation function results in:

$$\Psi = J_v \Delta p + J_D \Delta \pi \quad (15)$$

The first term in Eq. 15 describes the total volume flux J_v as function of the applied pressure, and the second term describes the diffusion flux of the salt J_D .

The new set of phenomenological equations is:

$$J_v = L_p \Delta p + L_{pD} \Delta \pi \quad (16)$$

and

$$J_D = L_{Dp} \Delta p + L_D \Delta p + L_D \Delta \pi \quad (17)$$

By applying different experimental conditions to the Eqs. 16 and 17, the phenomenological coefficients can be determined from experimental measurements.

Assuming no pressure difference is applied, i.e., $\Delta p = 0$, then the diffusive flux is given by:

$$(J_D)_{\Delta p=0} = L_D \Delta \pi \quad (18)$$

and the volume flux is given by:

$$(J_v)_{\Delta p=0} = L_{pD} \Delta \pi \quad (19)$$

Assuming that there is no osmotic pressure difference, i.e., $\Delta \pi = 0$, then the diffusive flux is given by:

$$(J_D)_{\Delta \pi=0} = L_{Dp} \Delta p \quad (20)$$

and the volume flux is given by:

$$(J_v)_{\Delta \pi=0} = L_p \Delta p \quad (21)$$

The hydrostatic pressure difference at zero volume flux, i.e., the osmotic equilibrium is given by:

$$(\Delta p)_{J_v=0} = -\frac{L_{pD}}{L_p} \Delta \pi = \sigma \Delta \pi \quad (22)$$

Here, σ is the so-called Staverman reflection coefficient which is a measure for the permselectivity of a membrane.

Equation 22 shows that in osmotic equilibrium the hydrostatic pressure difference between two solutions separated by a membrane is equal to the osmotic difference $L_p = L_{pD}$ and therefore $\sigma = 1$.

This is only the case for a strictly semipermeable membrane. Usually, the Staverman reflection coefficient has values between 0 and 1.

If the volume flux is 0, the ratio of salt flux to osmotic pressure difference is given by:

$$\left(\frac{J_s}{\Delta\pi}\right)_{J_v=0} = \frac{C_s L_p L_D - L_{pD}^2}{L_p} = \omega \quad (23)$$

Here, ω is the permeability of the salt.

Combining Eqs. 13, 14, 18, 22, and 23 leads to:

$$J_v = L_p(\Delta p - \sigma \Delta\pi) \quad (24)$$

and

$$J_s = C_s(1 - \sigma)J_v + \omega \Delta\pi \quad (25)$$

Based on the phenomenological equations, the mass transport in reverse osmosis of a solution of a single salt solution can be described by three coefficients, i.e., L_p the hydrodynamic permeability of the membrane, ω the salt permeability, and σ the reflection coefficient. All three coefficients can be experimentally determined.

Comparing Eqs. 24 and 25 with Eqs. 5 and 6 which are based on the solution-diffusion model that for membrane with high salt rejection, i.e., $\sigma \approx 1$ and when kinetic coupling between the water and the salt flow is low which can be assumed in most reverse osmosis membranes the transport in reverse osmosis can adequately be described by the solution-diffusion model.

Mass transport in ultrafiltration

In ultrafiltration (UF) the driving force is a pressure gradient and the mass transport is dominated by the convective flux through pores (Strathmann et al. 2006). The principle of the process is depicted in Fig. 1.

As in microfiltration a porous membrane and a hydrostatic pressure difference is applied to separate certain components from a feed solution. However, the structure of an ultrafiltration membrane is asymmetric having the smallest pores on the surface facing the feed solution, and its pores are significantly smaller than those of a microfiltration membrane. Its diameters at the feed side surface of the membrane are between 2 and 10 nm, and the components retained by an ultrafiltration membrane have a molecular weight between 5,000 to several million Dalton. Since

Principle of Ultrafiltration (UF),

Fig. 1 Schematic drawing illustrating the principle of ultrafiltration

ultrafiltration membranes retain also some relatively low molecular weight solutes, osmotic pressure differences between the feed and the filtrate can be significant and diffusive fluxes of the solutes across the membrane are no longer negligibly low. Therefore, the flux of individual components in ultrafiltration can be expressed as a function of a hydrostatic pressure and a difference in the chemical potential of the different components between the feed and filtrate solutions. The volume flux, i.e., the filtration rate, is given by the sum of the fluxes of the individual components:

$$J_v = \sum_i J_i \bar{V}_i = \sum_i \bar{V}_i L_i \frac{d\mu_i}{dz} + L_v \frac{dp}{dz}$$

$$= \sum_i \bar{V}_i L_i \frac{d}{dz} (\bar{V}_i p + RT \ln a_i) + L_v \frac{dp}{dz} \quad (1)$$

Here J is the flux, L is a phenomenological coefficient referring to interactions of the permeating components with the membrane matrix, $\bar{V}_i$ is the partial molar volume, μ is the chemical potential, p is the hydrostatic pressure, z is a directional coordinate, a is the activity, and the subscripts v and i refer to volume flow and individual components.

The first term in Eq. 1 describes the diffusive fluxes of all components in the pores of the membrane and the second term the volume flow.

In ultrafiltration the total volume flux, i.e., the filtration rate in a dilute solution, can be expressed to a first approximation by the flux of the solvent, i.e., $J_v \cong J_w$, and the activity of the solvent in the solution a_w can be expressed by an osmotic pressure. Assuming a linear relation for the pressure and activity gradients across the membrane, integration of Eq. 1 gives the flux through an ultrafiltration membrane as a function of pressure difference between feed and permeate solution, the hydrodynamic permeability for the viscous flow, the osmotic pressure difference between feed and permeate solution, and the phenomenological coefficient determining the diffusive flow of water through the membrane pores:

$$J_v \cong J_w = \bar{V}_w^2 L_w \frac{\Delta p - \Delta \pi}{\Delta z} + L_v \frac{\Delta p}{\Delta z} \quad (2)$$

Here J_v and J_w are total volume and solvent fluxes, respectively, Δp and $\Delta \pi$ are the hydrostatic and the osmotic pressure gradients across the membrane, L_v is the hydrodynamic permeability, L_w is the diffusive permeability of the solvent, and Δz is the thickness of the selective barrier of the membrane.

In most practical applications of ultrafiltration, the first term of Eq. 2 can be neglected since $L_w \ll L_v$. The osmotic water transport will affect the membrane volume flux only when the

difference in osmotic pressure between the feed and permeate solution is significantly higher than the hydrostatic pressure difference. This is only the case for ultrafiltration of solutions containing a high concentration of retained components of relatively low molecular weight. Since generally only macromolecular components are retained, the volume flux, i.e., the filtration rate in ultrafiltration, can be described to a first approximation by

$$J_v = L_v \frac{\Delta p}{\Delta z} \quad (3)$$

For the transport of solutes through an ultrafiltration membrane, the diffusive flux can generally not be neglected and the flux of the solute through the membrane can be expressed as the sum of a diffusive flux due to a chemical potential driving force and a convective flux due to the concentration in the pore solution:

$$J_i = L_i \frac{d}{dz} (\bar{V}_i p + RT \ln a_i) + L_v {}^m C_i \frac{dp}{dz} \quad (4)$$

Here ${}^m C_i$ is the concentration of the solute in the pore solution.

It can be shown that for hydrostatic pressure, differences usually applied in ultrafiltration is: $\bar{V}_i p \ll RT \ln a_i$. If it is assumed that the activity coefficient of the solutes in the membrane is 1, the phenomenological coefficient can be expressed by the Fick's diffusion coefficient according to equation $J_i = -D_i \frac{dC_i}{dz}$. Introducing these approximations into Eq. 4 leads to

$$J_i = J_v {}^m C_i - {}^m D_i \frac{d {}^m C_i}{dz} \quad (5)$$

Integration of Eq. 5 over the membrane thickness gives

$$J_i = J_v \frac{{}^m C_i^f \exp \frac{J_v \tau \Delta z}{{}^m D_i} - {}^m C_i^p}{\exp \frac{J_v \tau \Delta z}{{}^m D_i} - 1} \quad (6)$$

Here J is the flux, C is the concentration, D is the diffusion coefficient, τ is the tortuosity factor, and Δz is the thickness of the membrane; the subscripts

i and v refer to solute and the volume; the superscripts m , f , and p refer to the membrane, the solution in the membrane at the feed side, and the solution in the membrane at the permeate side.

Equation 6 shows that the flux of a component i which is partly retained by the membrane in ultrafiltration consists of two terms. The first term represents the viscous flow and is a linear function of the hydrostatic pressure. The second term represents the diffusion in the pore liquid and is an exponential function of the hydrostatic pressure.

In ultrafiltration there are two limiting cases for the transport mechanism. In the first case, it is assumed that if the hydrostatic pressure and thus the viscous flow is zero, then the transport of a solute is determined by diffusion only, i.e.,

$$\lim_{J_v \rightarrow 0} J_i = 0 \quad (7)$$

The second limiting case is obtained when the pressure and thus the viscous flow is infinitely high. Then the transport of the solute is determined by its concentration in the membrane, i.e.,

$$\lim_{J_v \rightarrow \infty} J_i = J_v {}^m C_i^p \quad (8)$$

Since the flux of the solute in ultrafiltration is a function of the viscous flux, the retention of an ultrafiltration membrane is obviously a function of the applied hydrostatic pressure. It can be described by combining equation

$R_i = \left(1 - \frac{C_i^p}{C_i^f}\right)$ and Eq. 6 and by introducing partition coefficients to relate the concentrations of the solute in the feed and the permeate to that in the membrane. Thus is

$$R_i = 1 - \frac{k^f \exp \frac{J_v \tau \Delta z}{{}^m D_i}}{k^p - 1 + \exp \frac{J_v \tau \Delta z}{{}^m D_i}} \quad (9)$$

with

$$k^f = \frac{{}^m C_i^f}{C_i^f} \quad \text{and} \quad k^p = \frac{{}^m C_i^p}{C_i^p} \quad (10)$$

Here k_f and k_p are the partition coefficients which relate the concentrations in the feed and the permeate to that in the membrane. In most ultrafiltration membranes, the two partition coefficients are identical.

The effect of the hydrostatic pressure on the retention in ultrafiltration becomes more clear when two extreme cases are considered, i.e., a very large and a very small hydrostatic pressure difference between the feed and the permeate solution. At large pressure differences, the viscous flux is high and the retention approaches a maximum value which is determined by the distribution coefficient of the solute between the membrane and the solution:

$$\lim_{J_v \rightarrow \infty} R_i = 1 - k^f \quad (11)$$

At very low hydrostatic pressure the retention goes to zero:

$$\lim_{J_v \rightarrow 0} R = 0 \quad (12)$$

Process Control in Membrane Operations

Radoslav Paulen

Department of Biochemical and Chemical Engineering, Technische Universität Dortmund, Dortmund, Germany

Efficient automatic control system is an essential part of every plant being operated in chemical industry. It may be implemented for various reasons: plant and environmental safety, fulfillment of varying process demands, rejection of input disturbances, optimal production desire, etc.

Process control is usually achieved via feedback policy. By measuring time-varying process outputs $y(t)$ (controlled variables), such as temperature or concentration, one decides about process inputs $u(t)$ (manipulated variables), such as input power to heating cell or valve position, to attain some or all of the abovementioned goals.

Classical control theory defines a fashion in which obtained measurements are used to identify value of input as a control law. Its basic form can be stated as

$$u(t) = f(y(t))$$

where $f(\cdot)$ represents a function which can take various forms and can be designed using analytical or numerical methods in order to establish optimal, adaptive, robust, stochastic, or any other type of process control.

Process control can be designed by exploiting neural network or fuzzy logic approach. The latter technique was used to control microfiltration process by Perrot et al. 1996.

However, the most popular control applications are accompanied with the use of proportional-integral-derivative (PID) controller. Its control law can be written as

$$u(t) = K_p e(t) + K_i \int_0^t e(\tau) d\tau + K_d \frac{d}{dt} e(t)$$

where K_p , K_i , and K_d are proportional, integral, and derivative gains, respectively, and $e(t)$ represents control error, a difference between desired and actual value of the output. There are numerous applications of PID controller in membrane technology and processes (van Reis et al. 1997; Smith et al. 2005; Blankert et al. 2007; Yee et al. 2008).

Productivity and Footprint in Gas Separation

Adele Brunetti

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The productivity to footprint compares the productivity of the separation system with respect to the installation area occupied by the system itself (Eq. 1) (Criscuoli and Drioli 2007). Considering the same area occupied by the units, this metric identifies the most productive scheme to get a set target. Future plants should be characterized by high productivities and low sizes; therefore, a high value of this index is highly desired.

To compare two different technologies that can be used for the same separation, the ratio between the values of productivity/footprint ratio obtained for each of them can be defined (Eq. 2). When the value of this ratio is higher than 1, membrane operations should be preferred, whereas, for values lower than 1, traditional units should be chosen.

$$\text{Productivity}_i/\text{Footprint} = \frac{\text{Productivity}}{\text{Footprint occupied by the installation}} \quad (1)$$

Productivity footprint ratio

$$= \frac{(\text{Productivity}_i/\text{Footprint})^{\text{Membranes}}}{(\text{Productivity}_i/\text{Footprint})^{\text{Traditional technology}}} \quad (2)$$

Propane Oxidative Dehydrogenation by Membrane Reactor

Miguel Menendez

Department of Chemical and Environmental Engineering, University of Zaragoza, Zaragoza, Spain

Propene is industrially obtained in naphtha crackers, in FCC units, and in a growing proportion, by dehydrogenation of propane. Propane dehydrogenation is an endothermic reaction, and the maximum achievable conversion is limited by thermodynamic equilibrium. An alternative to propane dehydrogenation is the oxidative dehydrogenation of propane. In such case, the reaction is irreversible, but the inconvenience is the appearance of nonselective oxidation reactions of propane and propene to carbon oxides (CO and CO₂). The success of propane oxidative dehydrogenation will be linked to the achievement of high selectivity to propene and high enough conversion (Cavani et al. 2007). A large amount of research has been devoted to the optimization of the catalyst, and this is obviously a key factor, but the selection of a suitable reactor may be another factor contributing to achieve a successful result. A packed bed membrane reactor in which propane is fed at the catalyst bed entry and oxygen is permeated along the membrane provides a low partial pressure of oxygen in the reaction zone. For many catalysts, a low partial

pressure of oxygen implies a better selectivity to propene (Ziaka et al. 1993; Pantazidis et al. 1995; Tonkovich et al. 1996). The use of porous membranes has been reviewed by Coronas and Santamaría (1999) and Julbe et al. (2001).

Modifications in the Reactor Configuration

This approach has been employed by several researchers with a variety of modification in the configuration:

- Pure propane and homogenous oxygen distribution along the bed.
- Propane diluted with inert gas and/or oxygen diluted with inert gas. In comparison with the previous approach, safety is increased and often the selectivity achieved is better, but the industrial application would require the separation of inert gases from the reaction products, increasing the process operation costs.
- Nonhomogenous distribution of oxygen feed. In order to obtain a greater reaction rate at the reactor entry, a larger permeation of oxygen near the propane entry may be useful.
- Combination of a conventional fixed bed reactor with a membrane reactor. In such case, the feed to the fixed bed reactor contains a small amount of oxygen.
- The use of a catalytic membrane. In this case, part of the membrane is loaded with catalyst, preferentially in the side where propane is fed. The operation principle is the same as when a packed bed of catalyst is employed: the lower oxygen partial pressure in the reaction zone increases the selectivity to the desired product (Alfonso et al. 1999; Julbe et al. 2000).

Types of Membrane

The membrane employed for this reaction does not need to be selective for oxygen, i.e., a mesoporous membrane may be employed. In such case, the back permeation of hydrocarbon to the shell side must be avoided. This usually requires a significant

pressure drop of oxygen. Examples of membranes employed include microfiltration ceramic membranes with the pores filled with silica, nanofiltration ceramic membranes with enamel trips to reduce the permeation or zeolite membranes. In an alternative configuration, the membrane has catalytic activity (Alfonso et al. 1999).

Alternatively dense ceramic membranes, i.e., oxygen selective, can be employed (Wang et al. 2003; Czuprat et al. 2010). In such case, in addition to the improvement in propene selectivity provided by the oxygen distribution and the avoidance of back permeation problems, the previous step of oxygen separation from air may be avoided.

Catalysts

Although in principle any catalyst suitable for oxidative dehydrogenation of propane could be tested in propane dehydrogenation, the most employed are the simplest ones: vanadium oxide supported on alumina or on magnesium oxide.

Propolis Extract Nanofiltration

Beatriz Mello

UFSCar, Federal University of Sao Carlos, Buri, SP, Brazil

Propolis is a mixture of beeswax and resins collected by the honeybee from plants, particularly from flowers and leaf buds. Its composition depends on the type of plants accessible to the bees. There are changes in color, odor, and probably medicinal characteristics according to source and the season of the year. The major compounds are resins composed of flavonoids and phenolic acids or their esters, which often form up to 50 % of all ingredients. The variation in beeswax content also influences the chemical analysis. More than 500 different compounds from propolis through several regions were isolated, being impossible to determine their composition without first analysis.

Propolis composition is responsible for a lot of studies relating antimicrobial, antioxidant, anticarcinogenic and antifungal activities, among other health benefits. Thanks to these

characteristics, a great interest exists to use propolis for human consumption as being incorporated in drugs, cosmetics, and foods.

The most usual way to manipulate propolis is by its extract. Ethanol is the most common solvent used once it can extract the major constituents from propolis at low cost. Other solvents as water and propylene glycol are also studied.

The excess of solvents in extracts can be responsible for some limitation in industrial process, causing some variation in the final product, so it is necessary to concentrate it before use. The most traditional methods are lyophilization (freeze-drying), vacuum distillation, evaporation, and distillation. These methods require a high energy consumption and in some cases high temperatures that can degrade some functional compounds. To avoid these drawbacks, the method of nanofiltration has been studied for propolis concentration (Fig. 1).

Nanofiltration membranes are the same as reverse osmosis membranes; only the network structure is more open, causing a lower retention of monovalent salts (Mulder 1996). It has been widely used in concentration process where the objective is to retain functional compounds with low molecular weight, especially phenolic compounds.

Propolis nanofiltration has been studied for some authors recently, and the process showed a high efficiency in retaining flavonoids and phenolic compounds, which are of major importance to propolis quality, reaching more than 95 % rejection in concentration factor of 3.0 and 4.0. Moreover, the process had low fouling and concentration polarization, phenomena that can

Propolis Extract Nanofiltration, Fig. 1 Schematic diagram of propolis extracts nanofiltration process

Propolis Extract Nanofiltration, Fig. 2 Differences between conventional (a) and tangential filtration (b)

make the whole process inviable through flux decay (Tylkowski et al. 2010; Mello et al. 2010).

Application of this technology could increase the use of propolis in many industrial applications, in new research projects, and in the development of new products with functional properties. Furthermore, this process allows removal of the solvent from the extract, reducing the disadvantages associated with using alcoholic extractions, and being feasible the use of another solvent during extraction procedure. In the membrane process, the product is not submitted to high temperatures, and there is no change in the physical state of the solvent, which means that the functional properties of the compounds of interest are preserved and the process as a whole is energy saving.

Cross-flow nanofiltration experiments showed that the nanofiltration process can be feasible technology for medicine and nutritional additive production based on propolis extracts (Fig. 2).

Proteases in Membrane Bioreactor

Ranjana Das

Chemical Engineering Department, Jadavpur University, Kolkata, West Bengal, India

Protease (also termed peptidase/proteinase) refers to a group of enzyme system that conducts the protein catabolism by hydrolysis of the peptide bonds between composing amino acids in polypeptide chain forming protein.

The modification of protein by protease offers synthesis of a wide range of value-added compounds with improved functionality from diverse sources. The protein with little commercial values (yellow fin sole frame, alfalfa protein, sea cucumber gelatin) can be converted to value-added products (bioactive peptides) by enzymatic modifications (Jung et al. 2006; Kapel et al. 2006; Zhao et al. 2007). Depending on enzyme-substrate binding site in the polypeptide chain, the protease system is classified as exoprotease (side peptide bonds) and endoprotease (inner polypeptide bonds). The type of protease in effect (serine protease, threonine protease, cysteine protease, aspartate protease, glutamic protease, metalloprotease) decides the nature of amino acids at the side chain of the product peptides. The end use of the hydrolyzed protein fragment (peptides) specifies the protease type in use.

Proteases in Membrane Bioreactor,

Fig. 1 Operational set up for hydrolysis of sesame protein isolate in EMR (side stream recycle membrane bioreactor) and subsequent UF fractionation. 1 feeding line for protein isolate, 2 reaction vessel, 3 constant temperature bath, 4 stirrer, 5 peristaltic pump, 6 cross flow UF with 5kDa

membrane, 7 UF with 2kDa membrane, 8 UF with 1kDa membrane, F - feed, P_1 , P_2 , P_3 permeates, R_1 , R_2 , R_3 retentate (Reprinted from Enzyme membrane reactor in isolation of antioxidative peptides from oil industry waste: A comparison with non-peptidic antioxidants, Das et al. (2012), with permission from Elsevier)

Involvement of protease as catalyst for bioconversion is becoming favorable from consumer acceptance viewpoint and mild reaction condition. Though the enzyme systems have untarnished safety evidence, governmental legislation and regulatory agencies restrict the incorporation of enzymes as food additives, which have motivated the pharmaceutical and food processing industries to develop methods of efficient enzyme separation from reaction mixture that have subsequently raised the concepts of membrane bioreactor.

Membrane bioreactor combines reaction vessel and separation unit in a single piece of equipment in order to obtain the desired product profile of defined molecular sizes. The enzymatic membrane bioreactor (EMR) integrates the enzymatic reactions, product separation, and catalyst recovery in a single operational step. Membrane bioreactor helps to maintain the desired molecular size of the product by proper selection of membrane pore characteristics while the extent of reaction is controlled by residence time in the reactor. They do have implicit advantages since the enzyme is recovered and reused, which leads

to high productivity and increases enzyme utilization (weight of product per unit weight of enzyme) (Cheryan 1998, p. 454), reduces the possibility of enzyme inhibition by hydrolyzates (in case of enzymatic hydrolysis), and improves product purity. In addition, membrane process eliminates the side effect associated with other hydrolysis unit operations, since high temperature is not required for enzyme inactivation. In EMR, protease application for plant protein modification appears tricky due to the presence of unhydrolysable component (hydrophobic core in plant protein) in the feed, which lengthens the reaction time causing unfavorable substrate depletion and product inhibition.

The choice of membrane and membrane bioreactor configuration depends on the nature of desired products and properties of reaction system (substrate and catalyst). Among the usable standard membrane bioreactor configurations (submerged membrane reactor, recycle membrane reactor, and plug flow bioreactor), MBR with external ultrafiltration unit (recycle type) (Fig. 1) is advantageous for protease system to obtain the peptides as desired product, as the substrate and

biocatalyst are of the same order of magnitude and product and substrate are vastly different in magnitude (Cheryan 1998, p. 451) (Rios et al. 2004).

The earliest demonstration of membrane bioreactor concept was by Blatt et al. (1968) for hydrolysis of milk protein with α -chymotrypsin in dead-end stirred cells reactor. Cheison et al. (2011) has given a detailed list of the various proteins hydrolyzed in EMR including several plant proteins (cotton seed protein, soy protein, corn gluten meal, and sesame protein); animal proteins (fish skin, cod frame protein, yellow fin sole frame, alaska pollock skin, hoki frame

protein, fish collagen); and mammalian proteins (beef rump, milk, eggs, goat whey, casein, hemoglobin, bovine skin gelatin, bovine hoof and horn, and bovine colostrums). Modern utilization pattern implies EMR as a tool of continuous production of specific bioactive peptides (Table 1).

Protein Crystallization by Membrane Crystallization

Gianluca Di Profio

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

In a membrane crystallizer, the crystallizing solution is in direct contact with the membrane surface; therefore a solute–membrane interaction will occur in certain circumstances. In this technology, the membrane provides, in the same time, the physical support for mass inter-exchange in vapor phase thus generating supersaturation and the solid support to promote heterogeneous nucleation mechanism. This effect can be due to both the structural and chemical properties of the membrane surface: (1) the porous nature of the surface might supply cavities where solute molecules are physically entrapped leading, locally, to high supersaturation values suitable for nucleation, and (2) the nonspecific and reversible chemical interaction between the membrane and the solute molecules can allow to concentrate and orient molecules on the surface without loss of mobility (Kornberg and Darst 1991), thus facilitating effective interaction proper for crystallization. In the case of complex molecular systems like proteins, the different interaction mechanism is dependent on the patches, with different chemical properties, which are available on the molecular surface.

Hydrophobic and hydrophilic spots, positively and negatively charged functional groups, and hydrogen-bonding moieties are known to provide affinity for almost any kind of non-biological surface. Structural rearrangements of adsorbed molecules develop with solute–surface residence time and are considered as one of the driving forces of adsorption which contributes significantly to nucleation free energy changes (Horbett 1992). Furthermore, the solute–membrane interaction can provide specific solute–solute interaction pathways which would lead to the formation of specific crystal structures (Simone et al. 2006). When inducing heterogeneous nucleation, generally both the induction time and solute concentration necessary for the nucleation decrease, whereas the nucleation density increases on going from a prevalently homogeneous to a prevalently heterogeneous nucleation contribution.

From the classical nucleation approach, the energetic of nucleation concerns mainly the work to create a surface. If there is already a solid substrate in the system, this will decrease the work required to create critical nuclei and will increase locally the probability of nucleation with respect to other locations in the system. The total change in surface free energy will be lowered by favorable interactions between the aggregate and the substrate and unfavorable interactions between the crystallization medium and the substrate, due to the negative value of the second term in the equation above. Consequently, nucleation will be enhanced by increasing the surface area of the substrate. The nucleation work depends on two main parameters: the externally controlled supersaturation ratio and the material surface/solution composition-dependent interfacial energy. Molecules dispersed in solution are first adsorbed on the surface by means of nonspecific attractive interactions. The irregular structure may physically block the lateral migration of the adsorbed protein molecules into the concaves, so that they are forced to be packed into compact aggregates. The trapping of molecules on the surface may result in a relatively higher local supersaturation, which would increase the possibility of nucleation compared with that on an ideally flat

surface. Here, nucleation will follow with the formation of critical clusters comprising molecules forming suitable bond angles with their neighbors, while the molecules in a randomly packed compact structure may form a fractal cluster, which cannot work as a nucleus for crystal growth. Critical clusters then grow into crystals while the fractal clusters grow into larger clusters. This simple mechanism can be generalized to describe heterogeneous nucleation on irregular substrates such as porous surfaces. From a technological point of view, the control of surface porosity in producing membranes can be easily achieved, so that specific membrane nucleants, having the desired value of porosity which might be used to achieve the desired heterogeneous/homogeneous activation Gibbs energy ratio, can be produced.

Protein Fouling

Pierre Le-Clech

School of Chemical Engineering, The University of New South Wales, UNESCO Centre for Membrane Science and Technology, Sydney, NSW, Australia

In membrane processes, fouling is generally attributed to particulates, colloids, and organic and/or inorganic compounds. Organic compounds could originate from the water source itself (e.g., humic and fulvic substances in surface water) and/or from the microorganisms present in the effluent to be treated (e.g., macromolecules in domestic wastewaters). Within the

macromolecules groups, proteins and carbohydrates have been extensively studied because of their ubiquitous presence in many feed waters treated by membrane technologies. Proteins, in particular, have been observed to significantly impact on the filtration performances in the food and biotechnology industry (van Reis and Zydney 2007) and in the wastewater treatment and recycling (by membrane bioreactors, MBRs, nanofiltration, NF, and reverse osmosis (RO); Wang and Tang 2011).

Proteins are usually present in aqueous solution in a globular/colloidal form (i.e., compact and spherical shape). Their tertiary structure is expected to significantly change with the solution properties (e.g., pH, temperature, salt concentration, presence of other organics). Given their nature (i.e., polymers of amino acid units linked by peptide bonds), proteins present strong affinities with the polymeric surface of the membrane systems, and initial electrostatic interactions can be noticed even before filtration, during passive adsorption tests. Under filtration, the hydrodynamic drag force further increases the tendency of proteins to deposit on the membrane. More details on fouling mechanisms by proteins are available in the article “protein fouling mechanisms.”

While most of the academic studies have focused on pure model protein compounds like bovine serum albumin (BSA), protein fouling in industrial applications is expected to greatly vary in nature and intensity, depending on the type of the feed. For example, porous membranes can be used to concentrate protein solutions in the dairy industry and to filter clean water from activated sludge in MBRs. It is therefore evident that characterization of the relative role of proteins within the formation of the fouling layers remain a complex exercise. In addition, proteinous compounds are expected to denature and/or to aggregate to other materials within the feed matrix. As a result, the respective smaller or larger foulants will lead to different fouling mechanisms, generally difficult to characterize.

Many analyses can be used to measure the relative concentration of proteins in the feed

solution. The conventional Lowry method has been used by default over the years, but the numerous limitations related to this colorimetric test makes it quite unreliable (Drews 2010). Recently, the liquid chromatography-organic carbon detector (LC-OCD) has been used to fractionate the various organic elements within an aqueous sample. Thanks to its complementary organic nitrogen detector (OND), LC-OCD could also provide a quantitative assessment of the level of proteins. Finally, fluorescence techniques like excitation-emission matrix spectroscopy are another emerging tool for protein characterization.

Protein fouling can be easily detected by changes in permeability of the membrane system (i.e., flux decline or transmembrane pressure increase). However, a large number of more advanced characterization techniques have been proposed over the years to identify location and quantity of protein deposition on membranes (Chan and Chen 2004). Scanning electron microscopy (SEM), attenuated total reflectance Fourier-transform infrared spectroscopy (ATR-FTIR), and confocal microscopy are some of the most commonly used techniques.

Protein Fouling Mechanisms

Pierre Le-Clech

School of Chemical Engineering, The University of New South Wales, UNESCO Centre for Membrane Science and Technology, Sydney, NSW, Australia

Depending on the membrane systems under investigation, mechanisms for protein fouling will change greatly. Here are concisely reported three major types of protein fouling studied at length in the literature.

Pure Protein Filtration (Lab-Scale Studies)

Over the years, a large number of studies have focused on the characterization of fouling by protein compounds. Bovine serum albumin (BSA) has been generally used as a model macromolecule to mimic the impact of proteins on hydraulic and removal performances in membrane systems. While most of the early work was based on micro- and ultrafiltration (MF and UF), only recent studies have assessed in details the protein fouling mechanisms in nanofiltration (NF) and reverse osmosis (RO). In porous membranes like MF and UF, proteins are expected to adsorb into the polymeric membranes and to gradually block the pores. During long-term filtration, proteins form a cake layer on the membrane surface. Electrostatic interactions between proteins and membrane surface are often cited as the main parameter behind the mechanisms for the initial deposition of proteins occurring in membrane processes, including NF and RO. Severe fouling is generally detected near the isoelectric point of the membrane, for which the electrostatic repulsion forces are minimum. Once the surface of the dense NF/RO membranes is covered by the initial deposition of proteins, fouling mechanisms rely on proteins/protein interactions, and the intrinsic membrane

properties were reported to have insignificant impact during long-term filtration of BSA (Wang and Tang 2011).

Protein Fouling in Food Membrane Processes

Protein is ubiquitously present in many food streams requiring purification, concentration, or treatment by membrane processes. Examples include concentration and fractionation of milk and whey in the dairy industry, production of soy (or other vegetables) protein concentrates and isolates, all generally conducted by MF and UF. For those applications, protein fouling mechanisms are especially studied in order to recommend the most appropriate cleaning strategies to be implemented. As filtration occurs, convection of proteins to the membrane surface results first in concentration polarization, before fouling is detected through the formation of proteinous gel layer. In addition, the constant shear forces implemented as strategy for limiting fouling in those systems generally result in protein surface denaturation and gelation at high concentration. Finally, interaction and aggregation with other compounds (especially divalent ions) are also known to occur, making prediction and modeling of protein fouling very difficult (Li and Chen 2010).

Relative Role of Proteins in Biofouling/Biofilm Formation in Water and Wastewater Treatment

Proteins are also a critical part of the formation of biofouling and biofilm growth in membrane processes. In wastewater treatment and recycling, proteins usually originate from the microorganisms present and growing in the feedwaters. Microbial organisms tend to produce extra cellular polymers (EPS), such as proteins, carbohydrates, and lipids. Once in excess within the boundary of their cell walls, the EPS is then

released in the bulk solution. Both the proteins present around the cells and in a soluble form in the bulk are expected to participate to the formation of biofouling and biofilm on the membrane surface. While biofouling is described as the deposition of organic materials of biological origin (including proteins), further attachment of bacteria and colloidal particles onto the membrane through adhesive forces during filtration is expected to lead to the development of biofilm. As filtration occurs, nutrients and dissolved oxygen are provided to the deposited bacteria and the immobilized bacteria can therefore form the biofilm layer (Marselina et al. 2009).

Proteins separation by membrane operations

Membrane systems are used extensively in the purification of high-value proteins from natural sources (e.g., milk and blood plasma) and from the biotechnology industry. This includes the use of normal flow microfiltration for sterile filtration and bioburden reduction, depth filtration for the removal of cell debris and aggregated material, tangential flow microfiltration for initial product recovery, and virus removal filtration (van Reis and Zydney 2007). Ultrafiltration is used for protein concentration and buffer exchange, both for the conditioning of the feed between other unit operations and in the final product formulation. However, actual protein purification, which typically refers to the separation of a desired protein product from other protein impurities, is accomplished using either membrane chromatography or high-performance tangential flow filtration.

Membrane chromatography provides highly selective separations by exploiting differences in protein adsorption/binding interactions, analogous to what is done in column chromatography (Ghosh 2002). The membrane adsorbers used in these systems typically have relatively large pore size with the functional ligands attached to the inner pore surface throughout the membrane. Separations can be accomplished using ion exchange (i.e., charged) ligands, affinity ligands, and hydrophobic interactions. Zeng and Ruckenstein (1999) have reviewed the different base materials and surface modification chemistries that can be used to generate chromatographic membranes.

Transport through membrane adsorbers is typically dominated by the pressure-driven convective flow; diffusional limitations are much less pronounced than in conventional chromatographic beads. This can be particularly important in the purification of large biomolecules and viruses that can have difficulty accessing the internal pore space in chromatographic beads. Membrane adsorbers can be operated at much higher flow rates and with lower pressure drops than conventional chromatography columns, potentially reducing the processing time (Zhou and Tressel 2006).

There has been significant interest in using membrane chromatography for bioprocessing for more than 20 years, but there have been relatively few large-scale commercial installations.

However, recent improvements in membrane materials and chemistries, coupled with a greater appreciation of appropriate target applications, have generated renewed interest in this technology. This is particularly true for flow-through applications in which impurities are bound to the membrane while the product flows directly through the membrane (Zhou and Tressel 2006). This includes the removal of trace DNA, viruses, and endotoxins. Flow-through applications can take full advantage of the high linear velocities possible with membranes. Single-use membrane adsorbers can be very attractive in these applications because of the small amount of impurities that need to be captured. This eliminates the need for reuse studies at small scale and for regeneration and sanitization at large scale, both of which facilitate the development of flexible manufacturing processes (van Reis and Zydney 2007).

High-performance tangential flow filtration (HPTFF) is an emerging technology that uses ultrafiltration membranes for the separation of proteins without limit to their relative size (van Reis and Zydney 2007). This is in sharp contrast to conventional ultrafiltration processes that are generally thought to require a tenfold difference in size between the product and impurity for effective separation. HPTFF has been used to separate monomers from oligomers based on their difference in size, protein variants differing at only a single amino acid residue based on the difference in charge, an antigen-binding fragment from a similar size impurity, and a monoclonal antibody from host cell proteins (van Reis and Zydney 2007).

The high selectivity in HPTFF processes is obtained by exploiting a number of different phenomena. As originally described, HPTFF devices are operated in the pressure-dependent regime at or below the “transition point” in a plot of filtrate flux versus transmembrane pressure. This minimizes membrane fouling and takes advantage of concentration polarization effects to increase performance (Zeman and Zydney, 1996). Further increases in selectivity are obtained by using charged ultrafiltration membranes and by adjusting the solution pH and ionic strength to exploit differences in protein charge between the product and impurity. High degrees of purification

and yield are obtained using a diafiltration process in which the impurities are washed through the membrane and away from the highly retained product. It is also possible to collect the product in the permeate solution with the impurities retained by the membrane.

Protein recovery by membrane operations is synonymous with protein purification by membrane operations and is discussed under that listing.

Protein Separation by Charged UF Membranes

Andrew L. Zydney
Department of Chemical Engineering, The
Pennsylvania State University, University Park,
PA, USA

Charged ultrafiltration membranes can be used to significantly enhance the membrane selectivity,

Protein Separation by Charged UF Membranes, Table 1 Effect of membrane charge and solution pH on the selectivity for separation of albumin and an antigen-binding fragment. Impurity and product refer to the less and more retained proteins, respectively. Thus, selectivity is defined as $S_{\text{albumin}}/S_{\text{Fab}}$ at pH 5 and as $S_{\text{Fab}}/S_{\text{albumin}}$ at pH 8.4

Solution pH	Negative membrane	Positive membrane
5.0	3	120
8.4	200	5

Table adapted from Rohani and Zydney (2010)

making it possible to use these membranes for the separation of similarly sized proteins (Zydney and van Reis 2011). Charged ultrafiltration membranes can provide very high retention of like-charged proteins, enabling uncharged proteins and smaller impurities to be removed in the permeate (Zeman and Zydney 1996). Separations are typically performed at relatively low ionic strength (<10 mM) to enhance the electrostatic exclusion of the charged protein from the charged membrane.

The effect of membrane charge on the separation of bovine serum albumin (MW = 67 kDa, $pI = 4.8$) and an antigen-binding fragment (Fab) from a monoclonal antibody (MW = 45 kDa, $pI = 8.4$) is shown in Table 1. Data were obtained using an unmodified (negatively charged) polyethersulfone membrane and a prototype positively charged membrane. The Fab has a significant positive charge at pH 5, enabling a highly selective separation using the positively charged membrane, with the weakly charged albumin passed into the filtrate. In contrast, albumin has a significant negative charge at pH 8.4, with the negatively charged membrane providing high selectivity with the weakly charged Fab collected in the filtrate. These high selectivities were completely lost when using the membrane with the “wrong” charge at the given pH.

Electrically charged ultrafiltration membranes have been successfully used to separate protein variants differing at only a single amino acid residue, an antigen-binding fragment from *E. coli* host cell proteins, a monoclonal antibody from mammalian cell host proteins, and a model pegylated protein from the unreacted protein and

polyethylene glycol, among others (van Reis and Zydney 2007; Rohani and Zydney 2010).

Protein Separation by UF

Andrew L. Zydney
Department of Chemical Engineering,
The Pennsylvania State University,
University Park, PA, USA

Membrane processes have been used for bioseparations since well before the start of the modern membrane industry. For example, John D. Ferry’s review article on ultrafiltration in 1936 (Ferry 1936) described the use of membrane technology for enzyme concentration, analysis of bacteriophages and viruses, preparation of cell- and protein-free ultrafiltrates from biological solutions, and sterile filtration, although these systems were limited to analytical-scale processes due to limitations on the available membranes and modules.

There has been considerable interest in using ultrafiltration membranes for actual protein-protein separations, taking advantage of the relatively low cost, high throughput, and easy scalability of membrane systems. Most early efforts at protein separations using ultrafiltration were unsuccessful (Nakatsuka and Michaels 1992), although there were some notable successes in small-scale separations of model protein

systems. Considerable progress in this area has been made over the past 15 years, with specific applications in both the biotechnology industry for the purification of therapeutic proteins and in the fractionation of natural protein sources like whey, egg white, and blood plasma. The key to all of these processes is the development of ultrafiltration membranes/systems with high selectivity between the product of interest and the impurities, where the selectivity is defined as the ratio of the sieving coefficient for the more permeable species to that of the more highly retained species. Selectivities of 100 or greater have been obtained for model systems involving immunoglobulins and albumin, hemoglobin from albumin, lysozyme and albumin, and many others (van Reis and Zydney 2007; Zydney and van Reis 2011).

In most cases, protein separation was accomplished by operating the membrane device at relatively low transmembrane pressures, below the “transition point” as defined by van Reis et al. (1997). High selectivities are obtained by proper choice of both membrane and buffer conditions, with the latter chosen to maximize the difference in electrostatic interactions for the two proteins. For example, positively charged ultrafiltration membranes have been successfully employed for the purification of monoclonal antibodies from mammalian host cell proteins, with the positively charged antibody retained by the charged membrane, while the smaller (and weakly charged) impurities are washed into the filtrate. High yields and purification factors are obtained using a diafiltration mode to increase the removal of impurities.

Protein ultrafiltration has been successfully demonstrated for the purification of antigen-binding fragments (Fab) and monoclonal antibodies from host cell proteins (van Reis and Zydney 2007). Data for monoclonal antibody purification from a harvested cell culture fluid show identical performance, as determined by nonreduced SDS-PAGE and ELISA, for a non-affinity monoclonal antibody purification process using ultrafiltration, in combination with cation and anion exchange chromatography, compared to that of a process using protein A affinity

chromatography for the bulk of the purification (Zydney and van Reis 2011).

Proton-Exchange Membranes for Fuel Cells

He Bai¹ and W. S. Winston Ho²

¹Momentive Performance Materials Inc, Friendly, WV, USA

²Department of Chemical and Biomolecular Engineering, The Ohio State University, Columbus, OH, USA

A fuel cell is an electrochemical device that can directly convert the chemical energy of a fuel into electricity. It is regarded as a promising energy conversion approach in the twenty-first century and has received increasing attention worldwide. Among all types of fuel cells, the proton-exchange membrane fuel cell (PEMFC) is considered as the most promising candidate for small stationary power generators and automobiles due to its high

power density, relatively low operating temperature, and fast startup. Compared to inner combustion engines, PEMFCs can reduce pollution (with only water in emission when using hydrogen as fuel), increase energy efficiency (40–50 % for PEMFC vs. 20–35 % for inner combustion), and decrease the nation's dependence on foreign oil (Song 2002).

The proton-exchange membrane is a very important component inside a PEMFC, and its main functions include (a) separation of oxygen from the fuel, (b) conduction of protons, and (c) barrier of electrons. As summarized by Hickner et al., there are six common criteria critical to all high performance PEMs, including (1) high proton conductivity and low electron conductivity, (2) desirable thermal, chemical, oxidative, and hydrolytic stability, (3) desirable mechanical properties in both dry and hydrated states, (4) low permeability to both fuel and the oxidant, (5) low cost, and (6) capability of being fabricated into membrane electrode assemblies (MEAs). Majority of PEM materials rely on absorbed water and its interaction with acid groups for producing proton conductivity. Thus, in most cases, proton conductivities of PEMs increase with the increase of relative humidity (RH) (Hickner et al. 2004).

Dupont's Nafion[®] and other perfluorinated sulfonic acid membranes (e.g., Aciplex[®] from Asahi Kasei, Femion[®] from Asahi Glass, PRIMEA[®] Series of MEAs from W.L. Gore & Associates, etc.) are currently popular to use for low temperature (<100 °C) PEMFCs due to their high proton conductivity, desirable mechanical strength, and good chemical stability. However, some disadvantages, such as high cost and high dependence of proton conduction on the water content, seriously limit the industrial application of these membranes. It is desirable for a PEMFC to operate at high temperatures and low RHs since high-temperature operations can accelerate the reaction rates at the anode/cathode and increase the anode's tolerable level of CO in the fuel, and low humidity operations can facilitate the water management of the fuel cell system. The US Department of Energy has established a goal of 0.1 S/cm for the proton conductivity of the PEM, with target operating conditions at 120 °C and 50 % RH (Hickner et al. 2004).

Cost-effective and thermally stable alternative membranes, including sulfonated polyimide (SPI), sulfonated poly(arylene ether sulfone) (SPAES), sulfonated poly(aryl ether ketone) (SPAEEK), and polybenzimidazole (PBI)-based membranes, etc., have drawn interests in the past decade. SPI, SPAES, and SPAEEK copolymers are synthesized by copolymerization of sulfonated monomers (Hickner et al. 2004). These sulfonated copolymer-based membranes are still highly dependent on water content, and a hydrophilic component has been incorporated into the membrane for water retention (Bai and Ho 2011). But, the oxidative and hydrolytic stability of these copolymers needs to be further improved prior to long-term operations. On the other hand, H₃PO₄-doping has been identified as a successful approach for the application of PBI as high-temperature and low humidity PEMs (Li et al. 2009; Bai and Ho 2011). In this case, fuel humidification is not necessary in fuel cell operations due to the unique proton conduction mechanism by self-ionization and self-dehydration of H₃PO₄. In addition, the PBI polymer showed very desirable stability under fuel cell operations, even at high-temperature (>150 °C) conditions. However, acid leakage through such membranes during long-term fuel cell operations remains to be a concern. Significant research efforts are continuing in both academia and industry for the further improvement/development of perfluorinated, alternative hydrocarbon polymer-based and polymer/inorganic hybrid PEMs.

Pulp and Paper Industry and Membrane Operations

Mari Kallioinen

Lappeenranta University of Technology,
Lappeenranta, Finland

Synonyms

Paper industry and membrane operations; Pulp industry and membrane operations

Membrane technology has adapted to pulp and paper mill applications with the aim of decreasing water consumption, recovering and recycling valuable compounds, and reducing the environmental impact of the mills. Today (2013), the most common membrane application in the pulp and paper industry is coating color recovery from waste coating streams by ultrafiltration. Membrane technology is also used in the treatment of a wide variety of process streams and effluents. Depending on the application, the treatment is performed either with pressure-driven membrane filtration processes (micro-, ultra-, or nanofiltration or reverse osmosis) or with membrane bioreactors (MBR) (Mänttari and Nyström 2009; Nuortila-Jokinen et al. 2003).

Pulp and paper mill process streams and effluents form a heterogeneous group of waters, because every pulp and papermaking process has its special characteristics, which also affects its process and wastewater quality. Thus, every pulp or paper mill has different water and effluent qualities. Moreover, the primary motives for the use of membrane filtration vary depending on the production processes at the mill and local legislation, and therefore, every reuse application has specific quality criteria. For these reasons, it is not really possible to specify in details which membrane is the most feasible for pulp and paper applications or to set common quality requirements for process streams produced by membranes (Mänttari and Nyström 2009; Nuortila-Jokinen et al. 2003).

Pulp and paper mill process streams and effluents are very complex mixtures of compounds originating from the raw materials and from different chemicals. They contain wood-based compounds, such as polysaccharides, lignin and wood extractives and degradation products of the wood component, and, depending on their origin, chemicals or additives used in the processing of raw materials or in the manufacturing of the end products. When a complex mixture of this kind is treated, fouling can significantly be diminished by a feasible membrane choice. Usually, less fouling occurs when a hydrophilic membrane, which carries only a weak charge, is used (Mänttari and Nyström 2009; Nuortila-Jokinen et al. 2003).

Today (2013) pulp and paper mill processes are mainly water based. Tolerance to solvents is only seldom a significant factor in membrane choice. Requirements for the chemical stability of the membranes depend on the application. pH of the process streams and effluents varies depending on their origin from below 2 to 14 and some effluents contain oxidizers. Also temperature of the streams and effluents varies depending on their origin. Temperature can be close to 10 °C (effluent from the external water treatment) or higher than 100 °C (some process streams at pulp plants). Membranes might also be exposed to microorganisms capable of degrading membranes manufactured from cellulose-based materials (Mänttari and Nyström 2009; Nuortila-Jokinen et al. 2003).

Pulp and paper mill process streams and effluents contain fibers and other suspended solids. They have also high contents of colloidal material. Due to this, a comprehensive pretreatment is needed, when modules with high packing density are used (e.g., spiral wound modules widely used in water treatment). Another specific characteristic of pulp and paper mill applications is that the volumes of the streams needed to be treated are huge and extremely high membrane filtration capacities are demanded. High shear rate membrane modules can produce the high capacities and usually also tolerate the solids and high content of colloidal material in the feed stream. The high shear rate modules currently used in pulp and paper mill applications are typically tubular

modules or modified plate and frame constructions, for instance, the cross-rotational (CR) module (Metso Paper), in which the shear rate is generated by rotors near the membrane surface (Mänttari and Nyström 2009; Nuortila-Jokinen et al. 2003).

Purification of Plasma from Cholesterol by Immunoaffinity Membranes

Nilay Bereli, Handan Yavuz and Adil Denizli
Department of Chemistry, Biochemistry Division,
Hacettepe University, Ankara, Turkey

Coronary heart diseases are responsible for the 4.3 million deaths in all of Europe and also can cause lifetime disability. The annual economic cost is estimated to be 192 billion with a substantial increase (Harland 2012). Together with the high blood pressure, LDL cholesterol is widely recognized as one of the major risk factors in the development of coronary heart diseases because of its ability to build up in the lining of arteries to form

atheromas and fatty acid deposits (Bruckert 1999; Thompson 2003). In the case where dietary and drug therapy is insufficient to set safe blood cholesterol level, extracorporeal cholesterol removal techniques with different selectivity and specificity have been used. Plasmapheresis, cascade filtration, heparin induced LDL precipitation (HELP), thermofiltration, dextran induced LDL precipitation, and direct adsorption of lipoproteins are the examples (Blaha 2003). The most selective removal of LDL has been achieved by the use of monoclonal antibodies against the apoB100, the main protein component of LDL, as a ligand (Kane et al. 1975). This allows removal of harmful LDL without decreasing useful HDL and other plasma proteins. Conventional gel-bead columns have certain limitations especially when studying with viscous media such as human blood. Alternative carriers such as membranes, monoliths, and cryogels are designed to solve drawbacks of gel-beads such as high-pressure drop and flow rate limitations that limit efficiency of applications (Berele et al. 2011). In random immobilization of antibodies, they can bind to the polymer surface at many different points (Denizli 2002; Yavuz and Denizli 2003, 2005). This generally results in decrease in the antigen-binding capacity because the accessibility of the antigen-binding sites is prevented in most cases. Anti-LDL immobilization onto the polymeric carriers can be performed in an oriented mode to leave its antigen-binding fragments free. It can be done by either using Fc receptor proteins such as Protein A and Protein G, by using carbohydrate binding polymer in order to bind through the carbohydrate moiety, or by using artificial or digestion product Fab fragments. Immunoaffinity adsorbent obtained by oriented immobilization of anti-LDL onto the biocompatible PHEMA cryogel membranes show better LDL adsorption capacity (129 mg LDL/g) from hypercholesterolemic human plasma than random anti-LDL immobilized adsorbent (111 mg LDL/g) while the amount of anti-LDL bound in an oriented mode was the one third of the random immobilized. Nonspecific adsorption of other lipoproteins was very low in both cases. It has been also shown that these adsorbents can be

used many times without significant decrease in the adsorption capacity (Bereli et al. 2011).

PVA-Based Anion-Exchange Membranes

Mitsuru Higa
Graduate School of Science and Engineering,
Yamaguchi University, Ube, Yamaguchi, Japan

PVA-based anion-exchange membrane consists of poly(vinyl alcohol)(PVA) matrix and anion-exchange groups (positively charged groups); hence, anions selectively permeate through the membrane. PVA is one of the most popular polymers that has been used as a membrane matrix, because a film made from PVA shows good physical properties, high hydrophilicity, process ability, biocompatibility, and good chemical resistance.

PVA is a water-soluble polymer and does not have any anion-exchange groups. Hence, a PVA-based homogenous anion-exchange membrane (AEM) can be prepared easily by casting an aqueous solution of mixed PVA and polycations and then cross-linked PVA polymer chains. PVA is a semicrystalline polymer; thus, heat-treatment above the glass-transition temperature increases the crystallinity of the polymer, which acts as a physical cross-linking. PVA chains can also be chemically cross-linked using cross-linking agents such as glutaraldehyde(GA) as shown in Fig. 1. Hence, the degree of swelling of a PVA-based AEM, which plays an important role in its permselectivity for anions and membrane resistance, can be easily controlled by varying the annealing and/or chemical cross-linking conditions. The AEM thus obtained has a semi-interpenetrating network (semi-IPN) structure in which polycation chains are immobilized in the polymer cross-linked network matrix. The ion-exchange capacity of such membranes can be easily controlled by changing the polymer ratio of PVA to polycations. AEMs with a semi-IPN structure have been prepared by blending PVA and a polycation such as poly(acrylamide-co-diallyldimethylammoniumchloride), poly(allyl amine), etc. However, those electrodialytic transport properties are not enough to compete with commercially available homogeneous AEMs. An additional disadvantage of AEMs with semi-IPN structure is low long-term stability when immersed in solution due to the dissolution of uncross-linked water-soluble polyelectrolytes in the network into the solution. To avoid the problem of dissolution of uncross-linked water-soluble polycations, AEMs with IPN structure were prepared by blending PVA and a PVA-based copolymer-type polycation, such as poly(vinyl alcohol-co-methacryloyl aminopropyl trimethyl ammonium chloride) (Fig. 2). ED processes with PVA-based AEMs have potential applications to many industrial fields such as water treatment, food industry, medical supplies, acid recovery from pickling solution, wastewater treatment, etc. The AEMs will also be potentially applicable to polymer electrolytes for alkaline direct methanol fuel cells because the AEMs have low methanol crossover.

Q

Quantitative Structure-Property Relationships (QSPR)

René Ruby-Figueroa

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

QSPR models can be defined as empirical equations, used for estimating various physical or thermodynamic properties of molecules. A QSPR model can be described as follows:

$$P = a + b \cdot D_1 + c \cdot D_2 + d \cdot D_3 + \dots,$$

where P is the physical property of interest; terms $a, b, c, \dots$ are regression coefficients, and $D_1, D_2, D_3, \dots$ are parameters derived from the molecular structure, also referred to as descriptors. A variety of different types of descriptors can be used. The simplest types are constitutional or topological descriptors, such as the number of carbon atoms, and parameters describing types and order of the chemical bonds in the molecules. Various geometrical descriptors, including the principal moment of inertia, can also be used. The most important and also the most complicated descriptors are electrostatic and quantum chemical descriptors. The electrostatic descriptors are parameters which depend on the charge distribution within the molecule, including the dipole moment. An example of a quantum chemically derived

descriptor is the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energies (Dyckjær and Jóónsdóttir 2004).

The QSPR approach has been growing up in the field of drug design. In this field common approaches such as QSPR as well as quantitative structure-activity relationship (QSAR) are used. Application in other fields, such as QSPR, to model various physical properties of carbohydrates (Dyckjær and Jóónsdóttir 2004) and the development of QSPR models for the prediction of skin permeability (Neely et al. 2009) have been reported in literature. An interesting application linked with membrane processes is the development of QSPR models that consider the simultaneous correlation of organic solute rejection with multiple molecular parameters for RO membranes, with the potential for being applied to a broad range of compound classes (Libotean et al. 2008).

The development of QSPR model involves several steps: collection and preparation of data $\rightarrow$ molecular optimization and generation of descriptors $\rightarrow$ selection of descriptors $\rightarrow$ QSPR model building $\rightarrow$ model validation. Descriptor data can be obtained from literature, performing experiments, or calculations by using commercial software (e.g., Codessa software package) as well. Techniques such as PCA, genetic algorithms (GAs), and stepwise regression have been widely used to select optimal subset of descriptors. Linear and nonlinear models can be applied for

developing QSPR models. The nonlinear models were mainly developed based on artificial neural networks (ANNs) (Khajeh and Modarress 2013).

QSPR/QSAR models should be associated with appropriate measures of goodness of fit, robustness, and predictively, according with the guidelines proposed by the Organisation for Economic Co-operation and Development (OECD). In this sense, the assessment of QSPR models is established using statistical validation procedures which consist of measuring both internal model performance (goodness of fit and robustness) and external performance (predictively). In particular, the model performance should be evaluated with respect to the absolute and relative absolute average errors and standard deviation of the errors. Internal model validation is based on the leave-one-out procedure (LOO) cross-validation approach.

Despite the potential and power of this approach, applications in membrane technology are not so common yet.

Radiation-Induced Grafting

Tauqir A. Sherazi

Department of Chemistry, COMSATS Institute of Information Technology, Abbottabad, Pakistan

Grafting initiated by radiation technique is known as radiation-induced grafting or radiation-induced graft polymerization (see article graft polymerization). Radiation acts as an initiator in the grafting process which generates controlled concentrations of active sites, depending upon the irradiation type, rate, and dose, which are distributed almost evenly throughout the entire volume of the sample and initiate polymerization. Owing to high energy, radiation makes it possible to carry out the process in the solid or viscous state at substantially lower temperatures than in the case of traditional, chemical initiators.

Types of Radiation

A variety of high-energy radiations can be used for the grafting process (Heger 1990). This may include electromagnetic radiation, such as x-rays and gamma rays, or charged particles, such as beta particles and electrons. The commonly used gamma radiation source is CO^{60} which has a

long half-life of 5.3 years and emits radiation of 1.17 and 1.33 MeV (mean value of 1.25 MeV).

Methods of Radiation Grafting

Radiation-induced grafting could be proceeded by simultaneous irradiation or pre-irradiation technique.

In the case of the simultaneous irradiation method, the polymer is irradiated in the presence of a monomer under inert atmosphere. Since all the components of the system exposed equally to the radiation, it radiolyzed nonselectively. This process has impact on the kinetics of polymerization, and as a result, the extent of homopolymerization is always high in simultaneous radiation grafting. The pre-irradiation method, on the other hand, involves the activation of the base polymer prior to the grafting reaction. As a result, considerable structural changes take place during the irradiation of the polymer itself, which have their impact on the physical properties of the resultant membrane. During pre-irradiation, the radicals generated on the polymer chains and the radical at one chain may either combine with another radical from the adjacent chain leading to the cross-linking or undergo chain scission, thereby producing terminal unsaturation. The scission and cross-linking process also depends

upon the nature of polymer to be irradiated (Sherazi et al. 2008; Gupta et al. 2004).

Radiation-Induced Grafting Mechanism

The irradiation of polymers may cause homolytic fission and thus generates free radicals on the polymer. Since radiation is generating the radicals for subsequent grafting, thus the presence of any other initiator is not essential. The medium of irradiation is important which affects the grafting mechanism. If the irradiation is performed in an inert atmosphere, then radicals are formed, but if air or oxygen is present, then peroxides may be formed on the polymer. The lifetime of the free radical depends upon the nature of the backbone polymer.

The mechanism for pre-irradiation grafting and simultaneous grafting are as below:

Pre-irradiation Grafting (In an Inert Atmosphere)

As already described in the pre-irradiation technique, the polymer backbone is first irradiated in vacuum or in the presence of an inert gas to form free radicals. The irradiated polymer substrate is then treated with the monomer, in liquid or vapor state or as a solution in a suitable solvent.

Pre-irradiation Grafting (In the Presence of Air/Oxygen)

If irradiation performed in the presence of air or oxygen, hydroperoxides or diperoxides will be formed, depending on the nature of the polymeric backbone and the irradiation conditions. When the grafting has to be performed, these stable peroxy products are treated with the monomer at higher temperature. The peroxides undergo decomposition to radicals, which then initiate grafting.

Peroxy products have the advantage that these can be stored for long periods before performing the grafting step.

Simultaneous Irradiation Grafting

In the case of simultaneous irradiation technique, the polymer and the monomers are irradiated simultaneously, to form free radicals and subsequent addition.

Since the monomers are also exposed to radiation in this technique, thus homopolymer formation also takes place. The simple representation of the process is as below.

RAFT Chemistry

Damien Quemener
Institut Européen des Membranes, Montpellier,
France

RAFT chemistry is one of the most important preparation methods to synthesize high-

of the technology toward a commercialization stage. One solution found is to firmly bond the photocatalysts to the surface of the membrane, via a RAFT polymer incorporating chelating groups. For example, TiO_2 has been immobilized onto polypropylene membranes, thanks to the surface-initiated RAFT polymerization of acrylic acid (Yang et al. 2011). The same approach of surface-initiated RAFT polymerization has been explored to add new functionalities to the filtration membrane. Zwitterionic polysulfobetaine brushes have been produced on the top of a cellulose membrane for improving hemocompatibility and antifouling property (Yuan et al. 2013). Pore size tuning could also be achieved via RAFT chemistry by an initiation of the polymerization from the pore walls. The RAFT process is here required to highly control the polymer chain length and thus the pore size decreases. For example, a track-etched poly(vinylidene fluoride) membrane has been treated to functionalize its pore size as well as to decrease it via the RAFT polymerization of acrylic acid (Barsbay et al. 2013).

Reactive Air Brazing (RAB) for Gas Separation Membranes

Vesna Middelkoop

Flemish Institute for Technological Research – VITO, Mol, Belgium

Introduction

Reactive air brazing (RAB) is a technique that has been developed in the last 10 years for high-temperature joining purposes as an alternative to widely used glass or glass-ceramic sealants and other high-temperature joining techniques that were often found to be less reliable and suitable (such as diffusion bonding, reaction bonding, active metal brazing, or brazing of metallized ceramics) (Nicholas and Mortimer 1985; Chung and Iseki 1991; Kim et al. 2005a).

The RAB concept (see Fig. 1) holds the promise of providing durable, robust, heat-resistant, and gas-tight seals for ceramic-to-metal and ceramic-to-ceramic components of power generation ceramic membrane systems (mixed ionic-electronic conducting (MIEC) membranes for high-temperature hydrogen or oxygen separation) and various process applications (such as the coal-based integrated gasification combined cycle, IGCC) as well as solid-state electrochemical devices (such as solid oxide fuel cells (SOFCs) fuel gas reformers and electrochemical sensors) (Weil et al. 2005a, 2006a).

Method

RAB emerged as a technique for joining dissimilar materials (both in terms of their thermal

Reactive Air Brazing (RAB) for Gas Separation Membranes, Fig. 1 Schematic illustrations of the high-temperature applications of RAB sealing for: (a) large-scale membrane-based gas separation systems (either for oxygen or hydrogen separation; shown here is a hydrogen

separation membrane) and (b) planar SOFC stacks composed of interleaved layers of sealed ceramic membranes and metal interconnects (Reproduced from Weil et al. (2006a) with permission from Elsevier)

expansion coefficients and chemical stability) by utilizing a brazing alloy system made from a metal oxide (partially or fully) dissolved in a noble metal filler. When heated to the melting point (greater than the operating temperature of the ceramic-metal unit) the binary RAB braze under capillary forces fills the space between the two joining components, while the metal oxide content reactively modifies one or both faying surfaces (without degradation). Upon cooling a seal is formed that remains hermetic, mechanically strong and chemically resistant at operating temperatures (or at room temperature). The RAB process is readily performed in air without the need for a naked flame, fluxing agents, vacuum, or reducing gas atmospheres (Weil et al. 2003, 2005b). Typical RAB systems investigated include Ag-Cu_xO, Ag-V₂O₅, Ag-MoO₃, and Pt-Nb₂O₃ among which Ag-CuO is one of the most promising and best-studied RAB braze systems for MIEC oxide-based membranes (Weil et al. 2006b).

Examples, Challenges, and Prospects

Weil et al., pioneers in the RAB technology for MIEC-based device technology, carried out a series of wettability experiments by the sessile drop technique (contact angle measurements) to determine the effect of the addition of different CuO compositions on the wetting behavior of the noble metal on La_{0.6}Sr_{0.4}Co_{0.2}Fe_{0.8}O₃ (LSCF6428) and preoxidized FeCrAlloy substrates, two prototype materials for the (MIEC) ceramic-to-metal joining system. Following from the results of these experiments and subsequent microstructural and chemical analyses of the braze-substrate interfaces, Weil et al. conducted joining experiments using the braze compositions that exhibited the best wetting, namely Ag-2 mol % CuO and Ag-4 mol% CuO brazes heated to 1100 °C (Weil and Hardy 2002). Later studies by Hardy et al. on Ag-CuO/LSCF6428 joints, that were formed with compositions of CuO in a range of 1.4–16 mol%, demonstrated the efficacy of

Reactive Air Brazing (RAB) for Gas Separation Membranes, Fig. 2 Scanning electron microscope (SEM) comparison of braze-substrate interfaces of two BSCF-

steel joints brazed at 1050 °C using Ag – 16 mol% CuO and Ag – 3 mol% CuO fillers (Reproduced from Kaletsch et al. (2012b) with permission from ASM International)

RAB, optimal braze wettability, joint ductility, and resulting flexural strengths greater than 100 MPa (Hardy et al. 2004). In comparison, Kim et al. reported a maximum average strength of 221 MPa for Ag-CuO brazed polycrystalline alumina joints with a CuO content of 8 mol% (Kim et al. 2005a). Similarly, for yttria stabilized zirconia (YSZ) substrates and Ag-CuO brazes, the authors showed that with increasing CuO content of up to 8 mol%, both the wettability of the braze and the bending strength of the brazed YSZ joint increased (Kim et al. 2005b).

A recent study conducted by Kaletsch et al., looked into the effects of different Ag-CuO compositions on brazing $\text{Ba}_{0.5}\text{Sr}_{0.5}\text{Co}_{0.8}\text{Fe}_{0.2}\text{O}_{3-\delta}$ (BSCF5582) and austenitic steel (AISI 314) at 955–970 °C. Higher CuO content results in better wetting but appears to affect the local chemistry and microstructure of the interfacial regions of the brazed joints (see Fig. 2) resulting in poorer mechanical strength and porosity and inadequate seals and leaks. By contrast, the low CuO content filler (Ag-3 mol% CuO) in the BSCF5582-steel specimens did not promote the growth of the reaction layers at the interface with the braze, not even after annealing in air at 850 °C for 300 h (Kaletsch et al. 2012a, b). The latest results by Chen et al. highlight the engineering challenges ahead to ensure high-integrity RAB joints for oxygen transport membranes (OTM) with high

fluxes (such as $\text{BaCo}_{0.4}\text{Fe}_{0.4}\text{Zr}_{0.2}\text{O}_{3-\delta}$) integrated in high-temperature membrane-based applications such as emission-free coal-fired power plants (Chen et al. 2015).

Reclaimed Water, Membranes for

Ángeles Blanco and Daphne Hermosilla
Department of Chemical Engineering,
Universidad Complutense de Madrid, Madrid,
Spain

The recovery, or reuse, of effluents from municipal wastewater treatment plants (MWWTPs),

commonly called municipal wastewater reclamation, represents a viable alternative to water shortage and contributes to an integral sustainable water management. This is an important alternative water source for many regions. There are no universal water quality standards defined for the reclaimed water, but health hazard is the main issue always mentioned within all available legislations (EPA and AID 2004; EPHC et al. 2006; EU 2000; OAL 1978, amended in 1998; Winpenny et al. 2010). The most viable treatment train for these effluents depends mainly on the final water use, considering its risks and constraints (Table 1), and the particular permit requirements. Additionally, it also depends on the level of water stress and availability, the geographical situation, the stakeholders' acceptance, and the economic figures.

Each reclamation case is defined by the final water use that must be directly connected to its specific treatment. The removal efficiencies that may be achieved after applying different technological alternatives, to reclaim municipal wastewater, are summarized in Table 2 (Asano et al. 2007; Ordóñez et al. 2014, 2011).

Conventional tertiary treatment (typically, flocculation + clarification + filtration + disinfection) is usually applied when reclaimed water would just be used for less strict uses, as agricultural irrigation, whereas membrane filtration is required for more exigent uses to avoid any health hazard or risk. In this framework, the main processes used for the retention of microbial and suspended solids are microfiltration (MF) and

ultrafiltration (UF) (Judd and Jefferson 2005). These treatments produce water for environmental or industrial uses, as cooling water, or they are applied as pretreatments for nanofiltration (NF) or reverse osmosis (RO), which are required to generate water of very high quality, even drinking water, as in Singapore (Wang et al. 2008).

Although almost any membrane design can be applied for the treatment of wastewater with low suspended solid content, only specifically designed membranes and operation modes would be able to handle effluents carrying high amounts of solids, bacteria, or organic pollutants, very frequent in effluents from MWWTPs. In these cases, higher cross-flow velocities or submerged systems may be a good option, including membrane bioreactors (MBRs) (Judd 2006; Ordóñez et al. 2014).

Regarding the current implementation of this technology, the main world cores are Australia, Asia (Singapore and China), and the USA, mainly used for aquifer recharge, potable use, and industrial applications (Fig. 1).

Main Challenges: Fouling and Reject Stream Management

In general, dissolved organic matter typically present in effluents from MWWTPs (TOC $\approx$ 5–20 mg/L; BOD₅ $\approx$ 3–10 mg/L), together with other colloidal matter, may produce fouling. Furthermore, although salinity of these effluents is much lower than seawater ($\approx$ 1,500 versus 38,000 mg/L, respectively), scaling may be produced, moreover if the MWWTP receives a large amount of industrial wastewater (Ordóñez et al. 2011). In this case, special attention must be given to the industrial cleaning processes that may produce periods in the MWWTP in which the residual chemicals create membrane fouling.

To minimize fouling problems, membrane surface may be modified to further enhance their antifouling behavior (Judd and Jefferson 2005). Another strategy is the installation of aeration devices, mainly in MF and UF systems, to enhance surface membrane shear, but it highly increases the cost (Judd 2006). The selection of

Reclaimed Water, Membranes for, Fig. 1 Worldwide distribution of the main municipal water reclamation facilities reclaiming water through membrane processes (Adapted from Ordóñez et al. (2014))

the best cleaning strategy (type of chemical, cleaning conditions, and frequency) for backwash and cleaning-in-place (CIP) is the key to achieve both a constant membrane system performance and the lowest possible contribution to operational cost (Caothien et al. 2003).

Another significant problem is the production of concentrated streams. Different initiatives regarding the removal of hazardous components from concentrated streams have been reported, but although some compounds are removed, others equally dangerous remain. Special attention will be given in the future to the accumulation of emerging contaminants. The best management alternative for these streams would be finding direct applications for them, namely, recycle them.

Recovery of Antibiotics from Fermentation Broth Membrane Operations

Cristiana Boi

Dipartimento di Ingegneria Civile, Chimica, Ambientale e dei Materiali, Università di Bologna, Bologna, Italy

The first step in the recovery of antibiotics from fermentation broths is the separation of the cells from the liquid growth media. However, the purification process is different whether or not the product is intracellular or extracellular. In antibiotic production, either options are possible even if the majority of antibiotics, including penicillins, cephalosporins, and streptomycin, are extracellular products. When the desired product is intracellular, after a coarse liquid removal step, the cells are lysed to release the product. The clarification of the antibiotic is then performed to remove the cell debris. In both cases, since the antibiotics are relatively small molecules, a concentrate containing the solid biomass and a permeate containing the antibiotic and other impurities are obtained (Brites Alves et al. 2002).

The important steps of the antibiotic production process are the separation of mycelial cells, the chemical extraction of the active molecule, and the purification and crystallization of the target antibiotic (Lipnizki 2010). Cell harvest is generally carried out by rotary vacuum filters or by centrifugation, but, apart from the high energy consumption, with these techniques a complete

recovery is not possible since a large quantity of the antibiotic is entrapped in the solid cake. To increase the recovery, an extensive cake washing is required which entails further energetic costs. Membrane cross-flow filtration with ceramic membranes, or hollow fibers, is achieving widespread application as an alternative to conventional filtration and centrifugation, due to their low-energy requirements (Adikane et al. 1999). Moreover, the use of membranes permits the introduction of a diafiltration step to improve upon the yield of antibiotic recovery, without additional investment costs.

Microfiltration and ultrafiltration are feasible options, but the use of ultrafiltration is preferred since it retains also some surface-active components, such as proteins and polysaccharides, present in the fermentation broths which are responsible for emulsion formation. These emulsions are a severe problem in the subsequent extraction step since they may lead to product contamination, low extraction yields, high solvent losses in the extracted broth, and clogging of pumps or other separation equipment. The use of ultrafiltration, with an appropriate molecular weight cutoff (MWCO), retains the components responsible for emulsion formation and eliminates the need of anti-emulsion products, which can also cause an environmental pollution problem since chemical synthetic surfactants are difficult to degrade (Tessiera et al. 2005). The practice showed that ultrafiltration is an efficient technique for the recovery of antibiotics from fermentation broths. Ultrafiltration could significantly improve the extraction operation in terms of phase separation, elimination of the need for any de-emulsifier or wet agent, and increase extraction recovery and product quality (Koltuniewicz 2010).

Recovery of Polyphenols from Olive Mill Wastewaters by Membrane Operations

Alfredo Cassano

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Olives contain an appreciable amount of bioactive compounds such as polyphenols with remarkable health benefits. They are potent antioxidants and exhibit various other physiological activities including antiinflammatory, antimicrobial, antiallergic, anticarcinogenic, and antihypertensive activities (Obied et al. 2005).

The biophenolic fraction of olive oil comprises only 1–2 % of the total phenolic content of the fruits; the remaining 53 % and 45 % are lost in olive mill wastewaters (OMWs) and the olive cake, respectively. Typical biophenols occurring in OMWs are benzoic acid derivatives (4-hydroxybenzoic, protocatechuic, vanillic acids), hydroxycinnamic acid derivatives (ferulic, caffeic acids), tyrosol, homovanillyl alcohol, hydroxytyrosol, and oleuropein. These compounds represent a precious resource of potentially useful chemical substances (after their direct recovery or chemical transformation) for cosmetic and pharmaceutical industries and in food processing and food product conservation.

Several techniques have been proposed individually or in integrated forms to recover phenolic compounds from OMWs including solvent

extraction, supercritical fluid extraction, and chromatographic separation.

Membrane operations such as microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO), mostly in sequential form, represent useful technologies for the recovery, purification, and concentration of polyphenols with regard to their molecular weight cutoff values. They offer significant advantages over conventional methodologies in terms of low energy consumption, no additive requirements, and no phase change.

Integrated membrane processes based on the use of these operations permit to obtain purified water which can be discharged in aquatic systems according to national regulations or to be used for irrigation. NF is typically employed for the separation of most part of phenolic compounds (Paraskeva et al. 2007).

Recovery of Polyphenols from Wine Wastewaters by Membrane Operations

Alfredo Cassano

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Grape seeds and pomace (a solid material consisting of skins and grape seeds) are typical by-products of the winemaking process containing phenolic compounds.

Recovery of Polyphenols from Wine Wastewaters by Membrane Operations,

Fig. 1 Purification, fractionation, and concentration of polyphenols from wine wastewaters by integrated membrane process

Grape seeds contain basically (w/w) 40 % fiber, 16 % essential oil, 11 % protein, 7 % complex phenolic compounds, sugars, minerals, and other substances (Campos et al. 2008). Grape skin is a source of anthocyanidins and anthocyanins, natural pigments with antioxidant properties.

These phenolic compounds have an extremely high market value as food additives, nutraceuticals, and cosmeceuticals, due to their biological activity (Crespo and Brazinha 2010).

A membrane-based process scheme for the purification, fractionation, and concentration of phenolic compounds from wine wastewaters is depicted in Fig. 1. The purification step devoted to the removal of undesirable compounds (such as fats, proteins, and sugars) and microorganisms is based on the use of ultrafiltration (UF) membranes.

The use of appropriate nanofiltration (NF) membranes allows for obtaining fractions enriched in phenolic compounds. The final concentration step with removal of the extracting solvent (as permeate) is performed by reverse osmosis (RO).

Regeneration of the Ion-Exchange Resin

Tongwen Xu

Collaborative Innovation Center of Chemistry for Energy Materials, School of Chemistry and Material Science, University of Science and Technology of China, Hefei, China

Regeneration of the ion-exchange resin is the procedure for recovering the ion-exchange capabilities of exhausted ion-exchange resins. Most ion-exchange resins are used in columns. Ion-exchange operation is basically discontinuous: a loading phase, called service run, is followed by regeneration of the exhausted resins (Calmon 1986). Regeneration ratio is calculated as the total amount of regenerant (in equivalents) divided by the total ionic load (also in equivalents) during one cycle. It is also equal to the number of eq./L regenerant per eq./L of resin operating capacity. A (theoretical) regenerant ratio of 1.00 (i.e., 100 %) would correspond to the stoichiometric quantity. Nevertheless, all resins need a certain excess of regenerant above the stoichiometric

Regeneration of the Ion-Exchange Resin, Fig. 1 Illustration of co-flow regeneration (CFR) (Dardel and Arden 2008)

Regeneration of the Ion-Exchange Resin, Fig. 2 Illustration of reverse flow regeneration (RFR), including (a) upflow loading and downflow regeneration and (b) downflow loading and upflow regeneration (Dardel and Arden 2008)

quantity. The regeneration ratio is influenced by the technological process, the type and amount of regenerant, etc. There are two main methods for the regeneration process (Dardel and Arden 2008): (1) co-flow regeneration, where the fluids are flowing from the top to the bottom of the column both during the service run and during regeneration (Fig. 1), and (2) reverse flow regeneration, where the fluids are flowing alternatively upward and downward during service and regeneration (Fig. 2). Traditional regenerants are salts (such as NaCl, KCl, NH_4Cl), acids (HCl, H_2SO_4 , HNO_3 , acetic acid, citric acid), and alkali (NaOH, KOH, NH_3 , Na_2CO_3). For instance, NaCl is normally used to regenerate SAC resins in the softening process. SAC resins need to be regenerated with a strong acid for the purpose of decationization, and SBA resins are always regenerated with NaOH in the demineralization process. The disadvantages of the use of traditional regenerants are the low regeneration efficiency and the discharge of large amount of wastewater, leading to serious environmental pollution and resource waste. Improvement methods include (1) the recovery of the discharged wastewater; nanofiltration can be utilized for recovery of the wastewater, or the waste can be used to produce composite flocculant; (2) the modification of the regenerants; alcohol, ketone, and surfactant are added, or new regenerants are developed; and (3) the strengthening of the regeneration process. Ultrasonic, microwave, electrodiagnosis, or thermal treatment is applied for the strengthening.

Regenerative Medicine by Membrane Operations

Antonella Piscioneri

Institute on Membrane Technology, National Research Council of Italy, ITM–CNR, Rende, Italy

According to the definition given by Daar and Greenwood in 2007, *regenerative medicine* “is an interdisciplinary field of research and clinical applications focused on the repair, replacement or regeneration of cells, tissues or organs to restore impaired function resulting from any cause, including congenital defects, disease, trauma and ageing” (Daar and Greenwood 2007).

At the basis of regenerative medicine, there is an interdisciplinary approach that combines the contribution of different scientific branches such as stem cell biology, developmental biology, gene therapy, tissue engineering, and material sciences. This short definition will be mainly focused to the contribution given to regenerative medicine by tissue engineering and material sciences through the development and the introduction of membrane constructs and membrane operations. The development of new membrane systems allowed to elicit specific cell responses and to keep functional differentiated cells satisfying one of the most prominent issues in the field of regenerative medicine. The literature reports different approaches of membrane systems that use cell cultures in a therapeutic device or as in vitro model system for the screening of new therapeutic molecules on cell metabolism.

Within the membrane system, the cells proliferate, migrate, and differentiate into the specific

tissue while secreting the extracellular matrix (ECM) components required to create the tissue. It is evident, therefore, that the choice of the material is essential for the development and replication of an appropriate microenvironment for controlling and directing the cellular behavior and promoting specific cell interactions. It has been demonstrated that the suitability of polymeric membranes for regenerative medicine purposes is highly dependent on the tissue that needs to be engineered. The histological, physiological, and biomechanical properties of each tissue determine the success of the regenerative process, therefore restricting the choice of the material suitable for the specific application. When materials are implanted into the body, cells encounter a very unfamiliar environment that could negatively affect their viability. The use of polymeric membranes allows to overcome this issue, representing an ideal substrate for regenerative medicine application, since membranes can mimic the extracellular matrix with which cells interact allowing the organization of the cells into a three-dimensional architecture. The great advantage of using polymeric membranes in a regenerative medicine application is the possibility to tune the surface structures in order to provide the tissue-specific cues. Increasing cell affinity can be achieved by binding to the membrane surface-specific biomolecules that stimulate the specific cell substrate interaction able to drive cell behavior toward the tissue regeneration. An example of mimicking the natural ECM of surface modification is given by the incorporation of signal peptide such as RGD (Arg-Gly-Asp) which is a peptide with a characteristic sequence of many adhesive extracellular matrix proteins and can bound many integrin receptors. This kind of modification, thus, facilitates cell recognition and cell recruitment leading to tissue regeneration. An example of RGD-modified membrane is the bio-functionalization to improve blood biocompatibility and tissue regeneration promotion properties of vascular graft. Biodegradable RGD-modified (Zheng et al. 2012) PCL tubular grafts have been tested both *in vitro* and *in vivo* in terms of

adhesion of platelet adhesion, infiltration, endothelialization, and as final step smooth muscle regeneration. After *in vivo* implantation in the carotid arteries of rabbits for 2 and 4 weeks, on the RGD-modified graft was observed a consistent reduction of platelet adhesion without any aggregation indicating an improvement of the graft biocompatibility. The presence of the biomolecule on the membrane surface promoted a deep cell colonization within the tubular scaffold, and the PCL-RGD graft was completely covered by a layer of endothelial cells, and a smooth muscle regeneration was observed, with characteristics similar to the one of the native artery.

Polymeric membranes, for their selective transport properties, can be also used for cell encapsulation, representing a possible tool for cell transplantation and release of specific molecules (growth factors, proteins, etc.) opening new application in regenerative medicine. The polymeric membrane immunoisolates the entrapped cells preventing the direct contact with the host immune system component; moreover, governing the mass transport of molecules, it recreates a suitable micro-environment allowing the perfusion of nutrients toward the cell compartments and the controlled delivery of the specific products. The cells encapsulated within the polymeric membranes can have different sources of origin according to the specific application and therefore can have a broad use, treating different pathological conditions in order to promote the regeneration of the organ functions such as in the central nervous system disease, diabetes, or liver failure and induce cartilage and bone regeneration as well as cardiovascular tissue regeneration (Hernández et al. 2010).

One innovative approach is the cell encapsulation using microfibers that can contain a variety of cells (Kang et al. 2014). An innovative approach (Onoe et al. 2013) led to the realization of functional microfibers able to form cell fibers that have been characterized for muscle, blood vessels, or neuronal network formation.

Within the wide field of regenerative medicine, in which membranes represent a support and a template able to promote the specific tissue district

regeneration, a peculiar example is given by the use of membranes as neuronal scaffold, either for the development of peripheral nerve conduits or to be used as a guidance in spinal cord injuries (SCI). In order to bridge a peripheral nerve gap, the three-dimensional structure of the membrane scaffold plays a significant role in neuron adhesion and neurite outgrowth; as a result nerve guidance channels (NGCs), such as hollow fiber membranes, have been deeply investigated for the promotion of nerve regeneration. Along single tube membranes, also multichannel tubular membranes have been proposed with the aim to mimic the more complex distribution of the bundle of nerve fibers.

In a nerve tube design, the membrane can be made up of biodegradable and nondegradable polymer, and good mechanical properties are one of the major issues in order to offer an adequate support to the cells in contact with. Good permeability qualities are necessary in order to allow the diffusion of nutrient and oxygen since the pore size and distribution determine the mass transfer of bioactive molecule that influences the nerve regeneration process. Another important aspect in the design of a membrane nerve guidance is represented by the topographical cues such as the recreation of highly aligned membrane scaffold that are able to promote the longitudinal elongation of the nerve toward the distal nerve stump in order to fill the gap. For instance, the use of aligned nanofibrous nerve conduits can enhance axon regeneration in rat sciatic nerve transection model.

Further strategies that are aimed to enhance the membrane performance in promoting the nerve regenerative process are represented by the incorporation of biochemical cues such as neurotrophic factors (NFs) and extracellular matrix (ECM) proteins which are delivered at the local lesion site in order to sustain tissue regeneration (Marquardt and Sakiyama-Elbert 2013; Gu et al. 2014).

Neuronal tissue regeneration is just one of the many applications of membrane systems for regenerative medicine. Current strategies for the development of an ideal membrane support for tissue regeneration are based on the combination of physiochemical and biological parameters that

are needed to mimic the *in vivo* microenvironment, which generates a functional product matching the clinical standards.

Release of Antimicrobial Agent

Sacide Alsoy Altinkaya
Department of Chemical Engineering, Izmir
Institute of Technology, Urla, Izmir, Turkey

Antimicrobial packaging is produced by adding active ingredients in the packaging system or

coating/immobilizing active agent onto the surface and/or using actively functional polymers that satisfy conventional packaging requirements. The use of antimicrobial packaging has received great attention since these types of systems provide high food quality, safety, and long shelf-life by reducing, inhibiting, or retarding the growth of microorganisms. Traditionally, antimicrobial agents are directly mixed into the initial food formulations in an excess amount since this approach may result in a decrease in the concentration of the antimicrobial agent on the food surface due to its diffusion into the interior parts of the food. Antimicrobial packaging offers an alternative way to overcome these limitations.

Controlled release of the antimicrobial agent from the film to the food surface is one of the most important desired properties of the antimicrobial packaging materials. A rapid release causes fast consumption of the agent in a short period of time; thus, protection of the food ceases, on the other hand, spoilage reactions on the food surface may start if the release rate of the antimicrobial agent from the film is too slow. Controlled release of the antimicrobial agent can overcome this limitation by continuously replenishing it to the food surface, compensating for the consumption or degradation of active compounds. Controlled release of drugs has been used for some time, and procedures for achieving desirable rates are well established, on the other hand, research on the development of food packaging films with controlled release properties are limited. Strategies used to control the release rate of antimicrobial agent from the packaging are mainly based on changing the degree of cross-linking (Buonocore et al. 2004) or asymmetric structure of the film (Gemili et al. 2009) or forming multilayer structured films (Han and Floros 1998). The release of the antimicrobial agent from the film involves first diffusion within the film toward the film/food interface, mass transfer across the interface, and dispersion into the bulk food. In most cases, diffusion in the film is the slowest and the rate-controlling step. In laminated multilayer systems, the outer layer is generally used to prevent loss of

the antimicrobial agent to the environment. The matrix layer contains antimicrobial agent and has usually amorphous structure to provide space for entrapping large amount of the antimicrobial agent and fast diffusion of the antimicrobials. The inner layer is the key layer to control the initial lag period and the flux of the antimicrobial agent. Therefore, the thickness of this layer and its structural characteristics are optimized to control the release rate of the antimicrobial agent. When highly swellable polymers are used as packaging material, in addition to diffusion of the antimicrobial agent, diffusion of water into the matrix and the rate of swelling of the matrix are also important factors that control the release rate of the antimicrobial agent. In cases where the characteristic diffusion time is lower than the relaxation time of the polymer, relaxation becomes the limiting phenomena controlling the solvent uptake, consequently the release of the antimicrobial agent. Food packaging materials based on proteins or polysaccharides are usually charged at the pH of the release medium. When both the antimicrobial agent and the food packaging material are charged, then the release rate depends on the pH of the release medium. In this case, the release of the agent occurs only if both the agent and the polymer are similarly charged since this condition promotes repulsion between them. Thus, the choice of the polymer matrix for the charged antimicrobial agent should be done based on the pH of the target food.

Reliability in Gas Separation

Adele Brunetti

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The reliability takes into account the on-stream factors which can cause unscheduled shutdowns. It is an important project consideration, particularly if the process is a primary source of make-up hydrogen to a hydroprocessor or other main-stream refinery processes (Miller and Stöcker 1989; Brunetti et al. 2010).

Membrane systems are extremely reliable with respect to the on-stream factor. The membrane separation process is continuous and has few control components which can cause a shutdown. Typically, the response to unscheduled shutdowns is rapid. Absorption systems are moderately reliable. The large equipment associated with the process for avoiding the formation of degradation and corrosion products and the presence of particles can cause unexpected shutdowns.

PSA systems are also moderately reliable. The numerous valves associated with the process can induce unscheduled shutdowns. The new PSA are designed with alternate modes of operation, in which 100 % of design capacity can be achieved while bypassing any failed valve or instrument, with only a slight loss of recovery. Failures are automatically detected and bypassed by the microprocessor-based control system. However, stronger and periodic control cycles are required.

The cryogenic process is considered by refiners to be less reliable than the PSA or membrane processes; this is mainly due not to the process itself but to the need for feed pretreatments. Failure of the pretreatment system usually results in contaminants freezing in the cold box, leading to shutdown. In this case, a “thaw” is necessary prior to restart. The pretreatment system itself is often more complex than the cryogenic system.

Removal of Antibiotics from Wastewaters by Membrane Operations

Cristiana Boi

Dipartimento di Ingegneria Civile, Chimica, Ambientale e dei Materiali, Università di Bologna, Bologna, Italy

Antibiotics are persistent pollutants present in wastewaters originating from the pharmaceutical industry, but, due to their extensive human and veterinary use, they have also been found in municipal wastewaters. It has been observed that conventional activated sludge (CAS) wastewater treatment is not sufficient for the removal of antibiotics, and their presence in wastewater effluents is considered one of the causes of the emergence of antibiotic-resistant organisms. Several approaches have been proposed for the removal of antibiotics from wastewaters, the more promising being membrane bioreactors (MBRs), membrane filtration, and advanced oxidation processes or a combination of the above (Michael et al. 2013).

Conventional wastewater plants were not designed to treat pharmaceutical compounds and, in particular, antibiotics, due to their highly variable chemical structure and properties. As a consequence, the efficiency of antibiotic removal varies according to the different antibiotic molecule. Another important issue is antibiotic concentration in the effluents, which depends on the origin of the wastewater stream. In wastewaters

coming from the pharmaceutical industry, the antibiotic concentration may be sufficiently high to require a pretreatment before the biological wastewater treatment. This could be necessary, because the presence of antibiotics restrains microorganism growth and may hamper the biological treatment processes (Lefebvre et al. 2014).

Among the suitable pretreatments, an important role is played by membrane processes with nanofiltration and reverse osmosis being more effective than ultrafiltration in antibiotic rejection. Removal rates for NF depend on the target antibiotic molecule, with removal higher than 80 % and as high as 95 % for macrolides. RO has shown 100 % removal rates, but higher energy requirements for the process and several drawbacks which include membrane compaction, fouling, and biological growth. It has been shown that the performance of RO in wastewater filtration can be dramatically improved by including a UF/NF prefiltration step (Zhang et al. 2006).

In municipal wastewaters, antibiotics and their metabolites are excreted by humans after administration and they are present in different varieties, but with lower concentration. In this case, application of either MBR systems, or advanced processing downstream of the conventional biological treatment, is crucial for antibiotic removal before effluent discharge. MBRs are more effective in the removal of antibiotics than CAS systems even if their cost is higher. The concentrate stream of the MBR system contains all the removed antibiotics, which can be efficiently degraded by ozonation (Senta et al. 2011; Liu et al. 2014).

Removal of Dissolved VOCs from Aqueous Solutions (Pervaporation Application)

Tadashi Uragami

Organization for Research and Development of Innovative Science and Technology (ORDIST), Kansai University, Suita, Osaka, Japan

Organic liquid/water selective membranes are effective for the removal of organics in water and recovery of organic solvents from water. These membranes can contribute to the environmental problem and effective use of organic solvents.

The removal of volatile organic compounds (VOCs) such as benzene and chloroform from aqueous benzene and chloroform solutions using poly(methyl methacrylate)-poly(dimethylsiloxane) (PMMA-g-PDMS), poly(ethyl methacrylate)-PDMS (PEMA-g-PDMS), and poly(n-butyl methacrylate)-PDMS (PBMA-g-PDMS) graft copolymer membranes was investigated by pervaporation (PV). When aqueous solutions of dilute VOCs were permeated through the PMMA-g-PDMS and PEMA-g-PDMS membranes, these membranes were Bz/H₂O- and CHCl₃/H₂O selective. The permeation and separation characteristics of the PMMA-g-PDMS and PEMA-g-PDMS membranes changed drastically at a DMS content of about 40 mol% and 70 mol%, respectively, as shown in Fig. 1. The permeation rate and VOC/water selectivity of the

Removal of Dissolved VOCs from Aqueous Solutions (Pervaporation Application), Fig. 1 Effects of the DMS content on the benzene concentration in the permeate and normalized permeate for an aqueous solution of

0.05 wt.% benzene through PMMA-g-PDMS (○), PEMA-g-PDMS (●), and PBMA-g-PDMS (□) membranes during PV

PBMA-g-PDMS membranes, however, increased gradually with increasing DMS content, unlike those of PMMA-g-PDMS and PEMA-g-PDMS membranes. Furthermore, TEM observations revealed that the PMMA-g-PDMS and PEMA-g-PDMS membranes had microphase-separated structures, consisting of a PDMS phase and a poly(alkyl methacrylate) phase. On the other hand, the PBMA-g-PDMS membrane was homogeneous. It was found that the permeability and selectivity of these graft copolymer membranes for treatment of aqueous VOC solutions by PV were significantly related to a PDMS continuous layer in the phase-separated structure (Uragami et al. 1999, 2001a).

Hydrophobically surface-modified membranes were prepared by adding a fluorine-containing graft copolymer to a microphase-separated membrane consisting of PDMS and PMMA to improve organic component selectivity. Contact angle measurements and X-ray photoelectron spectroscopy (XPS) revealed that the addition of a fluorine-containing copolymer produced a hydrophobic surface at the air side of the membrane due to surface localization of the fluorinated copolymer. It was apparent from TEM that adding a fluorine-containing copolymer of less than small

amount did not affect the morphology of the microphase-separated membrane. However, adding a fluorine-containing copolymer over a certain amount resulted in a morphological change, from a continuous PDMS phase to a discontinuous PDMS phase. The addition of a small amount of fluorine-containing copolymer to the microphase-separated membranes enhanced both their permeability and Bz/Chx selectivity for a dilute aqueous solution of benzene during PV because of their hydrophobic surfaces and microphase-separated structures. Specifically, the microphase-separated membrane with a small amount of fluorine-containing copolymer concentrated an aqueous solution from 0.05 to 70 wt.% benzene and, therefore, removed the benzene from water very effectively (Miyata et al. 2001).

PMMA-g-PDMS and PMMA-*b*-PDMS membranes containing tert-butylcalix[4]arene (CA) (CA/PMMA-g-PDMS and CA/PMMA-*b*-PDMS) were applied to the removal of benzene from a dilute aqueous solution of benzene by PV (Uragami et al. 2006). When an aqueous solution of 0.05 wt.% benzene was permeated through CA/PMMA-g-PDMS and CA/PMMA-*b*-PDMS membranes, these membranes showed high

Bz/Chx selectivity. Both the permeability and Bz/H₂O selectivity of the CA/PMMA-*g*-PDMS and CA/PMMA-*b*-PDMS membranes were enhanced by increasing the CA content, due to the affinity of CA for benzene. The permeability and Bz/H₂O selectivity of CA/PMMA-*b*-PDMS membranes were much greater than those of CA/PMMA-*g*-PDMS membranes. TEM observations revealed that both the CA/PMMA-*g*-PDMS and CA/PMMA-*b*-PDMS membranes had microphase-separated structures consisting of a PMMA phase and a PDMS phase-containing CA. The microphase-separated structure of the latter membranes was much clearer than that of the former and was lamellar. The distribution of CA in the microphase-separated structure of the CA/PMMA-*g*-PDMS and CA/PMMA-*b*-PDMS membranes was analyzed by differential scanning calorimetry (DSC), and CA was distributed in a PDMS continuous layer in microphase-separated structure (Uragami et al. 2001b, 2006).

It was found that a continuous PDMS layer in PMMA-*g*-PDMS and PMMA-*b*-PDMS membranes plays an important role for the removal of VOCs from water. For the purpose of constructing the membrane matrix from PDMS component mainly, polydimethylsiloxane dimethylmethacrylate macromonomer (PDMSDMA) was selected as a membrane material. The effects of cross-linkers of the cross-linked PDMS membranes derived from PDMSDMA and divinyl compounds were investigated, on the PV characteristics of the removal of benzene from an aqueous solution of dilute benzene. When an aqueous solution of 0.05 wt.% benzene was permeated through the cross-linked PDMSDMA membranes, they showed high Bz/H₂O selectivity. Both the permeability and Bz/H₂O selectivity of the membranes were enhanced with increasing divinyl compound content as the cross-linker and were significantly influenced by the kind of divinyl compound. PDMSDMA membranes cross-linked with divinyl siloxane (DVS) showed very high membrane performance during PV. The best normalized permeation rate, separation factor for Bz/H₂O selectivity, and PV separation index (PSI) (Huang and Rhim 1991) which is the product of the permeation rate and the separation factor

and can be used as a measure of the membrane performance during PV, of a PDMSDMA-DVS membrane, were 1.96×10^{-5} mkg (m²h)⁻¹, 98, and 192, respectively (Uragami et al. 2003). When divinyl perfluoro-*n*-hexane (DVF), which is much more hydrophobic, was employed as a cross-linker of PDMSDMA, the best normalized permeation rate, separation factor for Bz/H₂O selectivity, and PSI of a PDMSDMA-DVF membrane were 1.72×10^{-5} mkg(m²h)⁻¹, 4,316, and 7,423, respectively (Ohshima et al. 2005a).

In Table 1, the permeation and separation characteristics of various polymer membranes consisting of the PDMS components are compared under the same PV condition: feed solution, an aqueous solution of 0.05 wt.% benzene; permeation temperature, 40°C; and pressure of permeation side, 1.33 Pa. As can be seen in Table 1, both the normalized permeation rate and the Bz/H₂O selectivity of each of the CA/PDMSDMA-DVB, CA/PDMSDMA-DVS, and CA/PDMSDMA-DVF membranes were improved as compared to each of the PDMSDMA-DVB, PDMSDMA-DVS, and PDMSDMA-DVF membranes. Although the separation factors of the CA/PDMSDMA-DVB and CA/PDMSDMA-DVS membranes were lower than that of the PFA-*g*-PDMS/PMMA-*g*-PDMS membranes, the PSI of the former membranes was much greater than that of the latter one. In Table 1, it was found that the addition of CA into the cross-linked PDMSDMA membranes cross-linked with a suitable cross-linker is significantly effective to obtain higher permeation and separation characteristics. A CA/PDMSDMA-DVF membrane with DVF of 90 mol% and CA of 0.4 wt.% showed the best membrane performance, i.e., the normalized permeation rate, separation factor for Bz/H₂O selectivity, and PSI were 1.86×10^{-5} mkg(m²h)⁻¹, 5,027, and 9,350, respectively.

The air stripping removal of VOCs such as toluene and phenol from water by microporous polypropylene (PP) hollow fibers was studied. The VOC stream passed through the lumen side of the module, while air (stripping gas) flowed across the shell side. Experiments were performed

at different liquid flow rates (8–16 cm³ min⁻¹), gas flow rates (60–180 cm³ min⁻¹), feed VOC concentrations (100–1,000 ppm), and temperatures (24–35 °C). The removal was more effective when feed VOC level and liquid or gas flow rate increased. The applicability of a mass transfer model that considers diffusion in the liquid layer, membrane, and gas layer under steady state was checked. Unlike phenol with a very small dimensionless Henry's law constant (equilibrium gas concentration divided by liquid concentration) and a relatively low amount of sorption on PP fibers, the measured overall mass transfer coefficients for toluene reasonably agreed with those predicted from the model. The large deviation observed for phenol indicated unsteady state nature, likely due to its small concentration difference between air and liquid phase/fiber matrix (Juang et al. 2005).

Response Surface Methodology (RSM)

René Ruby-Figueroa

Institute on Membrane Technology, National Research Council of Italy, ITM–CNR, Rende, Italy

RSM consists of a collection of mathematical and statistical analyses used in the development of an adequate functional relationship between a response of interest y (referred to as response variables) and a number of associated factors (or input) denoted by $x_1, x_2, \dots, x_k$. For example, this approach can be exploited to find the levels of temperature (x_1), pressure (x_2), and flow rate (x_3) that maximize the permeate flux (y) in a membrane process. Therefore, permeate flux is a

function of the levels of temperature, pressure, and flow rate as follows:

$$y = f(x_1, x_2, x_3) + \varepsilon \quad (1)$$

where ε represents the random experimental error or noise observed in the response y . If the expected response is denoted by $E(y) = f(x_1, x_2, x_3) = \eta$, then the surface represented by

$$\eta = f(x_1, x_2, x_3) \quad (2)$$

is called as response surface.

Usually, a second-order model (Eq. 3) is used to find a suitable approximation for the true functional relationship between y and the set of selected factors:

$$y = \beta_0 + \sum_{i=1}^k \beta_i x_i + \sum_{i=1}^k \beta_{ii} x_i^2 + \sum_{i < j} \sum_j \beta_{ij} x_i x_j + \varepsilon \quad (3)$$

where y is the response variable (permeate flux for the previous example), β is the model constant, and ε is the residual (error or noise). The second-order model includes the linear x_i , quadratic x_i^2 , and interaction $x_i x_j$ effect for each factor (Montgomery 2001).

The main scope of RSM approach is to determine which factors and interactions are significant in contributing to the response being measured and those factors and interactions that are insignificant and do not contribute to either a particular response. In addition, an important objective is to determine the optimum settings of $x_1, x_2, \dots, x_k$ that result in the maximum, minimum, or target response over a certain region of interest.

In order to achieve these objectives, a series of n experiments should be carried out previously. In these experiments, the response y is measured for specified settings of the factors. The totality of these settings constitutes the so-called response surface design, which can be represented by a matrix, denoted by D , of order $n \times k$ called the design matrix:

$$D = \begin{bmatrix} x_{11} & x_{12} & \dots & x_{1k} \\ x_{21} & x_{22} & \dots & x_{2k} \\ \vdots & \vdots & \dots & \vdots \\ x_{n1} & x_{n2} & \dots & x_{nk} \end{bmatrix}$$

where x_{ui} denotes the u th design setting of x_i ($i = 1, 2, \dots, k$; $u = 1, 2, \dots, n$). Each row of D represents a point, referred to as a design point, in a k -dimensional Euclidean space (Khuri and Mukhopadhyay 2010).

It is crucial the proper choice of design in any response surface investigation, considering concepts such as orthogonality and rotatability, which affect the quality of model prediction. The most common designs applied in RSM are central composite design (CCD) and Box-Behnken design. CCD is obtained by augmenting a first-order design, namely, the 2^k factorial, with additional experimental runs, namely, the 2^k axial points ($-\alpha$ and α) and center-point (0) replications. The first-order design serves in a preliminary phase to get initial information about the response system and to assess the importance of the factors in a given experiment. The additional experimental runs are chosen for the purpose of getting more information that can lead to the determination of optimum conditions on the control variables using the second-degree model. On the other hand, Box-Behnken design provides three levels for each factor and consists of a particular subset of the factorial combinations from the 3^k factorial design. This design is popular in industrial research because it is an economical design and requires only three levels for each factor: minimum (-1), middle (0), and maximum (1); therefore, few experiments are needed. Other second-order designs are available but they are not frequently used as the ones already mentioned. Some of these designs include Hoke designs, Box-Draper saturated designs, uniform shell designs by Doehlert, and hybrid designs by Roquemore (Khuri and Mukhopadhyay 2010).

Once completed all the experiments and collected all the data for each response variables, it is possible to determine, by using the analysis of variance (ANOVA), the significance of each factor as well as interaction and quadratic effect. The

second-order model should be evaluated considering correlation coefficient (R^2), normal distribution of the residual, autocorrelation, and lack-of-fit test. If the model is adequate to describe the observed data, at the selected confidence level, the results can be represented by using contour plots, Pareto chart, main effect plot, interaction plot, and residual plot as well.

The determination of optimal conditions for one or multiple responses is determined by using the desirability function (DF). This method finds operating conditions that provide the most desirable responses. It is based on the conduction of experiments and fitting response models (y_k) for all k responses, the definition of individual desirability functions for each response (d_k), and the maximization of the overall desirability in comparison with controllable factors. For each response $y_k(x_i)$, a desirability function $d_k(y_k)$ assigns numbers between 0 and 1 to the possible values of y_k , with $d_k(y_k) = 0$ representing a completely undesirable value of y_k and $d_k(y_k) = 1$ representing a completely desirable or ideal response value. Depending on whether a particular response y_i has to be maximized, minimized, or assigned to a target value, different desirability functions $d_k(y_k)$ can be used. The individual desirability functions from the considered responses are then combined to obtain a total desirability function, $D(0 \leq D \leq 1)$ (Ruby-Figueroa et al. 2011).

This approach has resulted to be useful for developing, improving, and optimizing processes in which one or multiple responses of interest are influenced by several variables (factors) and the objective is to optimize these responses.

Responsive Membranes

► Magnetically Responsive Membranes

Retentate

Giuseppe Barbieri

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

The retentate is the whole mass leaving the membrane on the same side as the feed. It is collected in a volume or as a stream, leaving the membrane module in a batch or continuous operations, respectively. Together with the permeate, the retentate is one of the two outlets of a membrane unit. The other two streams are the feed and, optionally, the sweep.

Since no species can quantitatively/totally pass through the membrane except in the case of infinite permeation driving force, generally, it contains all the species feed to the membrane module.

Reuse of Paper Mill Effluents, Membranes for

Ángeles Blanco, Daphne Hermosilla and Carlos Negro

Department of Chemical Engineering, Universidad Complutense de Madrid, Madrid, Spain

The reduction of fresh water consumption in industry, particularly in the pulp and paper sector, is one of the main sustainable issues nowadays, and although water reuse within the process will reduce water consumption, the total closure of water circuits is limited by the increase of contamination load in process water, and moreover,

fresh water intake is always needed to compensate water losses. Therefore, the improvement of fresh water savings is moving to the regeneration and reuse of the final effluent of the mill, to obtain high quality water for replacing fresh water at critical points, and to the use of alternative fresh water sources as reclaimed water from municipal wastewater treatment plants (Ordóñez et al. 2014, 2010).

For treating the final effluent, paper mills operate different systems depending on the type and load of the wastewater. Usually, an equalization is performed followed by solids removal by physical or physicochemical methods. Subsequently, a biological treatment for the removal of dissolved biodegradable organic compounds is performed. Although the more applied biological treatment is aerobic, mainly activated sludge, nowadays anaerobic digestion is taking advantage due to its viability for producing energy and the reduction of sludge production (de Lemos Chernicharo 2007).

In this framework, to avoid any health and operational risk, membrane processes are being implemented as final tertiary treatment. In this sense, to control biofouling in the subsequent membrane treatments anaerobic treatment must be combined with aerobic treatment to reduce soluble organic matter in a higher extent that is 95 % (Bajpai 2000; de Lemos Chernicharo 2007). Moreover, effluents from biological treatments of paper mills are characterized by high solids concentrations, including fibers and bacteria flocs, among other residues of production. Hence, microfiltration (MF) or ultrafiltration (UF) are the necessary pretreatment for the wastewater inflowing a final nanofiltration (NF) or reverse osmosis (RO) unit (Speth and Reiss 2005). While MF is suitable for removing suspended solids, including larger microorganisms like protozoa and bacteria, UF may even remove viruses and organic macromolecules down to approx. 0.02 μm (Mallevialle et al. 1999; Speth and Reiss 2005). In general, UF is highly used in treatment plants reclaiming wastewater worldwide, and membrane bioreactors (MBRs) are taking advantage in different urban and industrial

applications because they operate in a submerged design, which requires low trans-membrane pressures (TMP), thus minimizing the effects of fouling and the problems related to filamentous bulking, so usual in paper mills (Judd 2006; Judd and Jefferson 2005; Ordóñez et al. 2014). Moreover, they may incorporate a higher dried solid concentration ($8\text{--}15\text{ g} \cdot \text{L}^{-1}$) than conventional activated sludge ($3\text{--}5\text{ g} \cdot \text{L}^{-1}$). Therefore, they produce less biological sludge. These properties also lead to lower hydraulic retention times and/or volumes required to perform the biological treatment in comparison to conventional systems (Judd 2006). Although, it is needed to consider that encased dead-end mode UF systems may entail a lower operational cost (Ordoñez et al. 2010, 2011).

As final step, to ensure a final water free of pathogens and of guaranteed quality for permitting stable operation conditions (mainly conductivity reduction), RO systems are recommended in any treatment train. However, in these systems scaling and fouling phenomena may cause decline in water production rates, low permeate quality, unsteady-state operation conditions, and serious damages in the membranes (Asano et al. 2007; Bickerton et al. 2011; Bonnelye et al. 2008; Judd and Jefferson 2005; Mallevialle et al. 1999). These are the current bottlenecks that paper mill managers must carefully deal, mainly with the scaling associated to silica and calcium compounds.

Synonyms

Electrodialysis reversal

Electrodialysis reversal (EDR) is a modification of the simple ED commercially introduced by Ionics in 1967 to overcome major electrodialysis shortcomings such as membrane fouling and scaling. In the EDR system, the polarity of the direct current applied to the ED stack electrodes is reversed at specific time intervals ranging from a few minutes to several hours (typically two to four times per hour) (Meller 1984). If the polarity is reversed, the negatively charged colloids will now be removed from the anion-exchange membrane back into the bulk and the membrane properties are restored. Not only colloidal materials but also freshly precipitated sparingly soluble salts are effectively removed from the membrane with this procedure before they can solidify.

In the reverse polarity operating mode, the hydraulic flow streams are reversed simultaneously with the reversed polarity, i.e., the diluate cell will become the concentrate cell and vice versa. During the reversal of polarity and flow streams, there is a brief period when the concentration of the desalted water exceeds the required product salinity. Therefore, the ED diluate outlet has a concentration sensor which controls an additional three-way valve. This valve diverts diluate with a too high concentration, the so-called off-spec product, into the ED concentrate or feed. Then, when the concentration drops to the specified value, the product flow is directed back to the product outlet. Thus, the necessity to clean the ED channels between changing the polarity causes some loss of overall efficiency as a certain amount of product is lost to the waste stream or has to be treated again. Employing the use of four-way valves instead of three-way ones enables one to decrease the amount of off-spec product during the reversal to some extent (Strathmann 2010).

In the classical EDR, the diluate and concentrate chamber dimensions as well as flow, and velocity of dilute and concentrate are equal. Thus, the concentrate is recycled to gain a high diluate recovery ratio. The resulting residence

time is thus very high, which limits the maximum permissible level of CaSO_4 and/or CaCO_3 supersaturation. The mean ion residence time (MIRTc) in a typical EDR design was estimated at ≥ 130 min (Myint et al. 2011). The resulting Langelier Saturation Index (LSI, determining the CaCO_3 precipitation risk) and CaSO_4 relative saturation level that are commonly used indices to control the scaling process are limited to 2.16 % and 200 %, respectively. The addition of mineral acid into the concentrate stream decreases the risk of CaCO_3 precipitation, while the addition of antiscalant, usually SHMP, shifts the scaling-free EDR operation to the region of gypsum saturation up to 300 % (Meller 1984). However, if comprehensive utilization of wastewater and controlled crystallization of $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ in the concentrate stream is considered, then any chemical addition is not allowed. Thus, a further increase in saturation level may be achieved only by decreasing the concentrate residence time value (Turek et al. 2007).

In terms of unit costs of desalination, EDR is comparable to RO for waters with TDS < 3000 mg/L, but it is especially suitable for the treatment of waters and wastewaters with high scaling and fouling potential.

Synonyms

Electrodialysis reversal in high supersaturation mode

The supersaturation level with sparingly soluble salts, mainly calcium carbonate and calcium sulfate, and resulting product water recovery in the classical electrodialysis reversal with recycling of ED concentrate are limited by a relatively long mean residence time in the concentrate loop (Myint et al. 2011). A substantial increase in scale-free operation at a high supersaturation level may be gained in a single-pass mode of operation only. In this case, the mean residence time (favorably accompanied by low variance of residence time distribution (RTD)) should be small when compared to nucleation time of crystallization of the sparingly soluble salt in question (Turek et al. 2006).

Electrodialysis was carried out in a single-pass mode with symmetric reversed polarity every 6–10 h. The problem of CaSO₄ precipitation was prevented by continuous removal of gypsum from

the brine in a separate precipitator, in which gypsum seeds were used to increase the rate of gypsum nucleation and significantly reduce the level of CaSO₄ supersaturation in the EDR concentrate (Korngold et al. 2005). It was found that antiscalant diminished the seeding effect on gypsum crystallization and increased the onset of crystallization time. Thus, it was demonstrated that the ED process combined with continuous CaSO₄ precipitation (in a separate precipitator) may be successfully carried out under a reverse polarity operation regime.

In a novel EDR design (Turek et al. 2006), different diluate and concentrate linear velocity values are applied instead of recirculation of concentrate. Thus, the concentrate's linear flow velocity is several times lower than the diluate's, so a certain diluate concentration decrement results in a several times higher increment in the concentrate salt concentration. At the same time, low residence time is gained due to a single-pass mode. The ED process with different diluate and concentrate flow velocities may be carried only when applying a thin, e.g., 0.19 mm, net spacer with high strand density that protects the membrane against bulging. The intermembrane distance also influences the rate of both diluate and concentrate salt content changes along the ED membrane. The amount of salt passing a certain membrane surface in a certain period of time results from the current density value. When added to a small volume of the solution, being inversely proportional to the intermembrane distance, it would increase its concentration to a large extent. The avoidance of concentrate recirculation and low mean residence time are the essential advantages of single-pass EDR. It was demonstrated that EDR in this mode can operate with no chemical addition at CaSO₄ saturation levels of Ca 500 % and +2.3 LSI (Turek et al. 2009, 2012). EDR carried out at small intermembrane distance and low residence time enables one to increase working time without changing the polarity and to decrease the ED

channel cleaning period between changing it. Both of these features result in an increase in product recovery and a reduction of the unit costs of desalination.

It was demonstrated that EDR in a single-pass mode can operate at a high supersaturation level which up till now has only been achieved with a chemical addition to the concentrate stream. The lack of antiscalants allows for the controlled crystallization of $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ and CaCO_3 in the concentrate stream. In the case of waters containing calcium sulfate and calcium bicarbonate as dominant solutes (over NaCl), crystallization of the aforementioned species might decrease the total concentrate salinity to a large extent. This will allow zero-discharge technology to develop (Turek et al. 2007, 2009).

Reversible Flux Decline

Pierre Le-Clech

School of Chemical Engineering, The University of New South Wales, UNESCO Centre for Membrane Science and Technology, Sydney, NSW, Australia

Synonyms

[Reversible fouling for constant pressure operation](#)

When constant transmembrane pressure (TMP) is applied to pressure-driven membrane processes, fouling formation on the surface results in flux decline. When operating conditions exceed a critical value, and/or when filtration is no longer sustainable, physical or chemical cleaning protocols are implemented to recover some of the original hydraulic performances. Specifications from membrane suppliers (or original equipment manufacturer (OEM) data) provide an approximation for the level of flux to be obtained for a given driving force.

The level of flux reversibility is proportional to the strength of the cleaning process and is generally slightly lower than 100 %. In other words, cleaning strategy can generally not guarantee full recovery of flux performances. The fraction of the flux recovered during cleaning is defined as the reversible flux decline (Fig. 1).

Reversible flux decline

Fouling remains one of the main drawbacks of pressure-driven membrane processes. However, a large fraction of the formed fouling can be easily removed by the large range of cleaning strategies available for the various membrane processes. These strategies include physical (i.e., relaxation,

backwashing for low-pressure systems) and chemical cleanings and are generally implemented in complement of fouling control methods (i.e., aeration in submerged systems, high feed cross flow velocities in pressurized membranes, etc.).

The degree of fouling reversibility is known to strongly depend on the frequency, duration, and strength of the cleaning method. As more energy and time are used during the cleaning episode, more foulants are expected to be removed from the membrane surface. It is also accepted that the rate of reversibility decreases with the time of cleaning, up to a point at which further cleaning does not remove a significant amount of foulant. This allows optimization of cleaning strategies for fouling reversibility. A reasonable trade-off between the maintenance costs due to cleaning and the loss of productivity due to decrease of hydraulic performances therefore remains a difficult task, and detailed cleaning strategies are generally provided by membrane suppliers.

Hydraulic resistance due to reversible fouling

The fouling propensity of a given feedwater can be quantified through the assessment of the additional hydraulic resistance resulting from the deposition of the fouling materials on the membrane surface. At the end of the filtration episode, the total hydraulic resistance (R_T) can be determined by using transmembrane pressure (TMP) and flux values, based on Darcy's law, as outlined in detail by Metzger et al. (2007). Specifically, the fouling resistance (R_F) can then be calculated by

subtracting the intrinsic membrane resistance (R_m) from R_T .

A method for advanced characterization of the fouling layer (and their relative resistance) was also proposed through a fragmentation method (Fig. 1, Henderson et al. 2010). In this method, the fouling layer was removed sequentially via a three-step cleaning procedure, whereby an increasing amount of strength was applied to detach the foulant layers from the membrane surface. This also helps to assess the preferential deposition of foulants on the membrane surface. Specifically, it is proposed to (1) rinse, (2) backwash, and (3) chemically clean the membrane, in that order. Operating details are provided in Henderson et al. (2010) for a small 0.01 m² hollow fiber modules. Upon removing each layer, a clean water test was undertaken to determine the residual resistance associated with the membrane (R_{Rinsed} , $R_{Backwashed}$, and $R_{Desorbed}$, respectively). Hence, the hydraulic resistance associated with each foulant layer (R_R , R_{BW} , R_D , and R_{IR} , respectively) was calculated using Eqs. 1, 2, 3, and 4.

$$R_R = R_T - R_{Rinsed} \quad (1)$$

$$R_{BW} = R_{Rinsed} - R_{Backwashed} \quad (2)$$

$$R_D = R_{Backwashed} - R_{Desorbed} \quad (3)$$

$$R_{IR} = R_{Desorbed} - R_m \quad (4)$$

Rheology of Emulsions

Anna Schuch, Heike Schuchmann and
Volker Gaukel

Food Process Engineering, Karlsruhe Institute of
Technology (KIT), Karlsruhe, Germany

Rheology is the study of deformation and flow of matter. Rheological characterization is thus on the one hand important to control membrane processes because viscosity determines wall shear stresses at constant velocity profiles. On the other hand it can be used to investigate structure and stability of emulsions as well as for characterization of the product properties.

For the description of rheological properties it is most often distinguished between viscous and elastic properties. Viscosity is the common measure to describe viscous properties resulting from internal friction in a fluid exposed to an external flow field. The dynamic viscosity η is defined as the ratio between applied shear stress τ and resulting shear rate: $\eta = \frac{\tau}{\dot{\gamma}}$. The kinematic viscosity ν is the dynamic viscosity divided by the density of the fluid ρ :

$$\eta = \frac{\nu}{\rho}. \quad (1)$$

A fluid is called “Newtonian” if viscosity is independent of the applied shear rate. If viscosity increases with increasing shear rate, the fluid is called shear thickening or dilatant. A fluid showing decreasing viscosity with increasing shear rate is called shear thinning or pseudoplastic. Elasticity means that energy is stored in a fluid and released at a later point of time.

The rheological behavior of a fluid can be characterized using different kinds of viscometers and rheometers. Devices like u-tube and falling sphere viscometers can only be used to characterize Newtonian fluids. On the other hand, rheometers enable the application of different shear rates and thus allow for a more detailed characterization of rheological behavior. High viscous products are characterized in capillary rheometers. Here, the fluid is forced through a pipe and orifice with known dimensions. For emulsions, shear rheometers are most commonly used. They measure the torque which is required to deform a fluid with an applied shear rate or vice versa. Different measurement geometries are used for fluids with different properties. Low viscous fluids like aqueous solutions are most often measured using Couette cells. Fluids of higher viscosity are in general measured in cone-plate systems. In order to not destroy complex fluids like emulsions, plate-plate systems are used. Shear rheometers can either be used at constant shearing or in oscillatory mode. For oscillatory measurements a sinusoidal shear deformation is applied and the resulting stress response is recorded. This measurement allows for gaining information about viscous as well as elastic properties of fluids (Metzger 2006).

Rheological behavior of emulsions is strongly influenced by their composition as well as by their structure (Derkach 2009). Emulsions behave like suspensions with solid spheres as long as the applied shear rate is low enough and the drops are small enough not to be deformed during the measurement. This means that the viscosity of emulsions is strongly influenced by their dispersed phase content. The higher the volume of the drop phase, the higher is the viscosity. For low dispersed phase contents (DPC), the relationship between DPC and viscosity is linear and the fluids are Newtonian. For intermediate DPC,

shear-thinning flow behavior occurs because the drops interact with each other and form clusters. The relationship between DPC and relative viscosity η_r is expressed by different mathematical equations. The Krieger-Dougherty equation is used quite often. With intrinsic viscosity η_i and DPC at closest packing DPC_p (Krieger and Dougherty 1959):

$$\eta_r = \left(1 - \left\{\frac{DPC}{DPC_p}\right\}\right)^{\eta_i \times DPC_p} \quad (2)$$

In addition to DPC , drop size distribution influences the rheological behavior because it determines the closest packing of the spheres. If emulsion drops are deformed, they show elastic behavior. This can either be caused by dispersed phase contents higher than the closest packing or by shear rates high enough to deform the drops.

Richardson Law

Fausto Gallucci

Chemical Process Intensification, Department of Chemical Engineering and Chemistry, Eindhoven University of Technology, Eindhoven, The Netherlands

The Richardson equation relates the permeation flux of hydrogen through dense membranes to the temperature, pressure difference, and membrane characteristics (Gallucci et al. 2007). In general, the hydrogen mass transfer mechanism through (Pd-based) membranes can be described by: (a) a traditional solution–diffusion mechanism for dense

membranes and (b) a Knudsen diffusion mechanism or combined mechanism of Knudsen diffusion and surface diffusion for porous membranes.

More in detail, the hydrogen permeation through a dense palladium layer is a complex process which consists of the following seven-step activated mechanism:

1. Mass transfer of hydrogen upstream toward the membrane surface and adsorption of hydrogen molecules on the membrane surface
2. Dissociation of hydrogen molecules on the same surface
3. Dissociation of the chemisorbed molecule into atomic form H^* consisting of a proton and an electron
4. Solution of the dissociated hydrogen atoms H^* into the lattice of the metal
5. Diffusion of the dissociated hydrogen atoms H^* through the lattice toward the downstream surface of the membrane
6. Recombination of H^* into hydrogen molecules H_2
7. Desorption of the H_2 molecules and mass transfer into the downstream bulk

For thick membranes, step 5 (diffusion of hydrogen atoms through the lattice) results in controlling the whole process. The diffusion of hydrogen atoms through the lattice can be described by the well-known Fick law:

$$J = D \frac{dc}{dx} \quad (1)$$

where J is the hydrogen flux through the lattice, D is the hydrogen diffusion coefficient, and c is the hydrogen concentration.

Under these conditions, the thermodynamic equilibrium between the hydrogen molecules in the gas phase and hydrogen atoms dissolved at the interface would be established and it can be described by

$$c = S \cdot p^n \quad (2)$$

where S is the hydrogen solubility and p the hydrogen partial pressure.

The hydrogen permeation at constant temperature through a dense palladium membrane is described by the following general expression:

$$J_{H_2} = P_{H_2} \frac{(P_{H_2, \text{upstream}}^n - P_{H_2, \text{downstream}}^n)}{t} \quad (3)$$

where J_{H_2} is the hydrogen flux through the membrane, P_{H_2} the hydrogen permeability, t the membrane thickness, p the hydrogen partial pressure, and n the dependence factor of the hydrogen flux on the hydrogen partial pressure, experimentally determined in the range 0.5–1 (Dittmeyer et al. 2001). When n is 0.5, the hydrogen flux follows the so-called Sieverts' law.

The hydrogen permeation through membranes is an activated process ruled by an Arrhenius law:

$$P_{H_2} = P_{H_2}^0 \exp\left(\frac{-Ea}{RT}\right) \quad (4)$$

where $P_{H_2}^0$, Ea , R , and T are the pre-exponential factor, the apparent activation energy, the universal gas constant, and the absolute temperature, respectively. Consequently, when n is 0.5, the hydrogen flux can be written in terms of the so-called Richardson equation:

$$J_{H_2} = P_{H_2}^0 \exp\left(\frac{-Ea}{RT}\right) \frac{(P_{H_2, \text{upstream}}^n - P_{H_2, \text{downstream}}^n)}{t}. \quad (5)$$

Sanchez and Lacombe Theory

Giulio C. Sarti

Department of Chemical Engineering, Mining and Environmental Technology, University of Bologna, Bologna, Italy

This is a molecular theory for classical fluids, based on a compressible lattice fluid (LF) model for the representation of the microstates of pure components and mixtures. Each molecular species is considered decomposed in a sequence of contiguous segments (r-mers). The lattice cells are either empty or occupied by a molecular segment of the components in the mixture. The volume of the cells is allowed to vary with composition. Statistical arguments are used to calculate the number of configurations available for a system of N molecules with given configurational energy and volume; the partition function is calculated from statistical mechanics results as a function of temperature and pressure, in a mean field approximation, and finally, a simple expression for the total Gibbs free energy is obtained for pure species (Sanchez and Lacombe 1976) and for mixtures (Lacombe and Sanchez 1976). In the derivation, the flexibility parameter of the r-mers and the close-packed volume of a molecule are assumed independent of temperature and pressure.

Relevant results of the theory are represented by the expression of Gibbs free energy:

$$\frac{G}{rNRT^*} = -\tilde{\rho} + \frac{\tilde{p}}{\tilde{\rho}} + \tilde{T} \left[\left(\frac{1}{\tilde{\rho}} - 1 \right) \ln(1 - \tilde{\rho}) + \frac{1}{r} \ln(\tilde{\rho}) + \sum_i \frac{\phi_i}{r_i} \ln(\phi_i) \right] \quad (1)$$

and by the expression of the volumetric equation of state:

$$\tilde{\rho}^2 + \tilde{p} + \tilde{T} \left[\ln(1 - \tilde{\rho}) + \left(1 - \frac{1}{r} \right) \tilde{\rho} \right] = 0 \quad (2)$$

Equation 1 has been written for the common case in which the number of configurations available for each r_i -mer in the close-packed pure state is unity. The quantities used by the model are defined in Table 1. The model expressions contain pure component parameters and one binary interaction parameter for each couple of components in the mixture.

The pure component parameters for a series of classical fluids are available (Sanchez and Lacombe 1976, 1978; Sanchez and Panayiotou 1994). The model can describe the liquid-vapor equilibrium conditions for pure components reasonably below the critical point (Sanchez and Lacombe 1976), as well as the phase equilibrium properties of different binary mixtures of simple classical fluids (Lacombe and Sanchez 1976), based on a single value of the binary interaction parameter; the latter value can be obtained from different experimental data for the mixture, i.e., from azeotropic temperature, change in volume or

Sanchez and Lacombe Theory, Table 1 List of symbols and properties used in the lattice fluid theory by Sanchez and Lacombe

	Symbol	Name	Definition/property
Pure component i	ρ_i^*	Characteristic density of pure component i	
	p_i^*	Characteristic pressure of pure component i	
	T_i^*	Characteristic temperature of pure component i	
	r_i^0	Number of lattice sites occupied by a mole of pure component i	$r_i^0 = \frac{M_i}{\rho_i^* v_i^*}$
	v_i^*	Volume occupied by a mole of lattice sites of pure substance	$v_i^* = \frac{RT_i^*}{p_i^*}$
	ε_i^*	Characteristic energy of pure component i	$\varepsilon_i^* = \frac{T_i^*}{k}$
Mixtures	N	Total number of moles	
	T	Temperature	
	p	Pressure	
	ρ	Density	
	ρ_i	Density of species i	$\rho_i = \omega_i \rho$
	ω_i	Mass fraction, $i=1,2,\dots,N_t$	$\omega_i = \frac{\rho_i}{\rho}$
	ϕ_i	Volume fraction	$\phi_i = \frac{\omega_i / \rho_i^*}{\sum_i \omega_i / \rho_i^*}$
	ρ^*	Characteristic density of the mixture	$\frac{1}{\rho^*} = \sum_i \frac{\omega_i}{\rho_i^*}$
	p^*	Characteristic pressure of the mixture	$p^* = \sum_i \phi_i p_i^* - \frac{1}{2} \sum_i \phi_i \sum_{j \neq i} \phi_j \cdot \Delta p_{ij}^*$
	Δp_{ij}^*	Binary parameter	$\Delta p_{ij}^* = p_i^* + p_j^* - 2(1 - k_{ij}) \sqrt{p_i^* \cdot p_j^*}$
	k_{ij}, Ψ_{ij}	Dimensionless binary parameter	$\Psi_{ij} = 1 - k_{ij}$
	r	Molar average number of lattice sites occupied by a molecule in the mixture	$r = \sum_i x_i r_i$
	T^*	Characteristic temperature of the mixture	$T^* = \frac{p^*}{r} \sum_i x_i r_i^0 \frac{T_i^*}{p_i^*} = \frac{p^* v^*}{R}$
	ε^*	Characteristic energy	$\varepsilon^* = \frac{T^*}{k}$
	v^*	Average close-packed mer molar volume in the mixture	$v^* = \frac{RT^*}{p^*}$
	$\tilde{\rho}$	Dimensionless density	$\tilde{\rho} = \frac{\rho}{\rho^*}$
	$\tilde{T}$	Dimensionless temperature	$\tilde{T} = \frac{T}{T^*}$
	$\tilde{p}$	Dimensionless pressure	$\tilde{p} = \frac{p}{p^*}$
		Volumetric equation of state	$\tilde{\rho}^2 + \tilde{p} + \tilde{T} [\ln(1 - \tilde{\rho}) + (1 - \frac{1}{r}) \tilde{\rho}] = 0$
	A	Total Helmholtz free energy	$\frac{A}{rNRT^*} = -\tilde{\rho} + \tilde{T} \left[\left(\frac{1}{\rho} - 1 \right) \ln(1 - \tilde{\rho}) + \frac{1}{r} \ln(\tilde{\rho}) + \sum_{i=1}^{N_t} \frac{\phi_i}{r_i} \ln(\phi_i) \right]$
	G	Total Gibbs free energy	$\frac{G}{rNRT^*} = -\tilde{\rho} + \frac{\tilde{p}}{\rho} + \tilde{T} \left[\left(\frac{1}{\rho} - 1 \right) \ln(1 - \tilde{\rho}) + \frac{1}{r} \ln(\tilde{\rho}) + \sum_{i=1}^{N_t} \frac{\phi_i}{r_i} \ln(\phi_i) \right]$

change in enthalpy upon mixing, mixture boiling point, UCST, and LCST (Lacombe and Sanchez 1976).

The model has been extended also to polymeric solutions (Sanchez and Lacombe 1978), considering that for the polymer species, the number of r-mers per molecule becomes infinitely large. The enthalpy of mixing of low molecular weight solutes in polymeric liquids may be well described by the model (Sanchez and Lacombe 1978). For polymeric mixtures the binary interaction parameters can be also reasonably predicted on the basis of the solubility parameters of the mixture constituents (Rodgers and Sanchez 1993). For its nature the model can describe well the equilibrium behavior of mixtures in the absence of strong polar interactions among the different components of the mixture.

Sand Filter

C. V. Vedavyasan
Department of Technology, Annamalai
University, Chidambaram, Tamil Nadu, India

Introduction

Sand filters are employed as primary treatment in a water/wastewater industry. Raw water with various particle sizes of colloids need to be

coagulated/flocculated with coagulants and flocculants. The filter is filled with media such as garnet, sand of varying sizes, and anthracite. These filters could be dual-media or multimedia based on the raw water characteristics. A very high degree of clarity is achieved in the filtered water on account of finer particles of garnet at the bottom which trap finer turbidity particles. Turbidity is trapped and held throughout the entire bed depth, rather than the top 1 or 2 in.

Mechanical filtration will remove almost all forms of turbidity. In many cases, filters containing specially graded and sized gravel and sand are effective in screening out turbid particles. With such units, a periodic backwashing to remove the filtered material is all the maintenance necessary.

Zeta Potential: This is a commonly used term in filtration. An increase or decrease of zeta potential along with pH is an important criterion in particle adhesion during the filtration process. This is the scientific term for electrokinetic potential in a colloidal system. Its value is related to the stability of colloidal dispersions. It also indicates the degree of repulsion between adjacent similarly charged particles in a dispersion.

Filter Comparison

	Sand	Depth
Media	Single	Three
Bed usage	1–3 %	90 %
Service rate	2–4 gpm/ft ²	7–10 gpm/ft ²
Backwash	15 gpm/ft ²	15 gpm/ft ²
Removal	40 μ	10 μ

Types of Sand filter

Filtration is used in addition to regular coagulation and sedimentation for removal of solids from surface water or wastewater. This prepares the water for use as a portable boiler or cooling makeup. Filtration is a simple mechanical process involving mechanisms of adsorption (physical

and chemical), straining, sedimentation, interception, diffusion, and inertial compaction.

- Dual-media filter
- Multimedia filter

The sand in a pool sand filter (# 20 silica sand; 45–55 mm) is specially graded to trap particles in the 20–100 μ range. The size and shape of the filter media affect the efficiency of the solids removal. Sharp, angular media form large voids and remove less-than-rounded media of equivalent size. Though most suspended solids are trapped at the surface or in the first 1–2 in. of bed depth, some penetration is essential to prevent a sharp increase in pressure drop. As a sand filter collects dirt, its efficiency increases, trapping more dirt. The media need to be sufficiently coarse to allow solids to penetrate the bed for 2–4 in.. It is time to backwash the captured dirt out of the filter. They need the lowest maintenance of the three types of pool filters. You may need to open up the tank every 5 years or so. Sand filters are the easiest to operate and maintain. If your sand filter requires frequent backwashing every week or two, the sand bed may be “mothballed,” or it may be “channeled.” It may calcify with calcium deposits. A properly sized sand filter could go over 10 years between sand changes.

The major advantages of dual media filtration are higher rates and the longer runs.

Soft swim require annual cleaning of the filter sand to prevent it from “gumming up.” High amounts of bather oils can gum up a sand bed.

Types of Media

Quartz sand, silica sand, anthracite coal, garnet, magnetite, and other materials may be used as filtration media. Silica sand and anthracite are the most commonly used types (e.g., in filters following a hot process softener where the treated water is intended for boiler feed, anthracite is usually used).

The terms “multilayer,” “in-depth,” and “mixed media” apply to a type of filter bed which is graded by size and density. Coarse

media, often 0.6–1.0 mm (0.024–0.04 in.) are used for closely controlled coagulation and sedimentation. Coarse, less dense particles are at the top of the filter bed, and fine, denser particles are at the bottom. Downflow filtration allows deep, uniform penetration by particulate matter and permits high filtration rates and long service runs. Because small particles at the bottom are also more dense (less space between particles), they remain at the bottom. Even after high-rate backwashings, the layers remain in their proper location in the mixed media filter bed.

The table below lists four media used in multimedia filtration. The use of too many different media combinations causes severe backwashing difficulties. High wash rates expand the magnetite layer which might wash away the anthracite from the filter necessitating high wash water.

Media in multimedia filters:

Media	Effective size, mm(in.)	Specific gravity
Anthracite	0.7–1.7 (0.03–0.07)	1.4
Sand	0.3–0.7 (0.01–0.03)	2.6
Garnet	0.4–0.6 (0.016–0.024)	3.8
Magnetite	0.3–0.5 (0.01–0.02)	4.9

Slow Sand Filtration (SSF)

Slow sand filtration technology is especially ideal for small communities required to use filtration to comply with new regulations.

How SSF Works

Slow sand filtration relies on both physical and biological activity in controlling plant pathogens. The filter bed in SSF is constructed of a medium with high surface area colonized by suppressive microorganisms. The media also presents a physical barrier to the passage of spores of plant pathogens (Figs. 1 and 2).

Advantages of SSF:

- It is low-energy consuming process.
- Has great adaptability in components and applications. Maintenance is minimal.
- Systems can be built and installed by laymen.

- Costs of building and running significantly lower than other disinfection methods.

In Australia, chlorination/bromination processes are most widely used for water disinfection in nurseries. Chemical treatments have

proven effective when used carefully; however, they are relatively expensive and present safety issues to the handlers and the environment.

A disadvantage of the SSF is the large amount of land required, a consequence of the slow rates of water filtration that are possible, typically only 10 % or less of the rates that are possible in rapid filtration.

Sand Filter, Fig. 1 A typical sand filter configuration

Sand Specifications

Sand is characterized by the diameter of the individual sand grain (0.15–0.35 mm) and the effective size of the composite sand, ES or d10. d10 is defined as the sieve size in mm that permits passage of 10 % by weight of the sand. The uniformity coefficient (UC) of sand is defined as d_{60}/d_{10} . Effective size (ES) is such that approximately 10 % of the total grains by weight are smaller and 90 % are larger. ES is the minimum size of most of the particles. Uniformity is measured by comparison of effective size to the size at which 60 % of the grains by weight are smaller and 40 % are larger. This latter size, divided by the

Sand Filter, Fig. 2 A typical slow sand filter for water purification

ES, is called the uniformity coefficient – the smaller the UC, the more uniform the media particle size.

It is recommended to use fine-grade sand (0.15–0.35 mm), uniformity coefficient (UC) always <3, preferably <2 and be washed free of clay, loam, and organic matter. Fine particles will quickly clog the filters and frequent cleaning will be required. Sand that is not uniform will also settle in volume, reducing the porosity and slowing the passage of water.

Biological Activity

Microbial activity builds up very quickly in greenhouse nutrient solutions, and slow sand filters become active in biological suppression without any special inoculation. Safe drinking water is a high priority for people without main facilities.

Slow gravity sand filters remove bacteria and other small particles from drinking water, making it safe to drink. Sand filters cannot cope with heavy metals or other excessive pollutants. Their prime purpose is to remove bacteria and particles. If the source of raw water has a high level of contamination, locate a new one. Even spring water or very clean water is to be checked for undesirable contaminants. If the water contains sediment, it should be passed through an initial settling tank before it gets into the sand filter.

How the Filter Works

The water passes through the sand from top to bottom. Any larger suspended particles are left behind in the top layers of sand. Smaller particles of organic sediment left in the sand filter are eaten by bacteria and protozoans which “stick” in the layers of slime that form around the sand particles, and the clean water which passes through the filter is safe to drink. Provided that the grain size is around 0.1 mm in diameter, a sand filter can remove all fecal coliforms (bacteria that originate from feces) and virtually all viruses.

Conclusion

Sand filters serve as the major equipment of filtration in every area of daily use – from swimming pools to household and water treatment plants. This primary treatment shall reduce the load on subsequent pressure filtration. Best engineering practices are advocated in the design of sand filters and operation thereafter for clear water suitable for downstream hygienic use. Clarifier effluents of 2–10 NTU may be improved to 0.1–1.0 NTU by conventional sand filtration.

Saturated and Supersaturated Solutions

Bart Van der Bruggen
 Department of Chemical Engineering, Process Engineering for Sustainable Systems (ProcESS), KU Leuven, Leuven, Belgium

A solution is saturated with respect to a given substance when the maximum solubility of the substance is reached. This is reflected by the solubility constant of the solution (Linke and Seidell 1965). For example, for the precipitation reaction:

The solubility is determined by the equilibrium constant of the reaction, K_{AB} :

$$K_{AB} = [A^{n+}][B^{n-}] \quad (2)$$

$$\text{or } \frac{[A^{n+}][B^{n-}]}{K_{AB}} = 1 \quad (3)$$

with $[A^{n+}]$ and $[B^{n-}]$ the activities of A and B, respectively. The logarithmic form of this equation is the stability index, SI:

$$SI = \log \frac{[A^{n+}][B^{n-}]}{K_{AB}} \quad (4)$$

When $SI = 0$, the solution is saturated. When $SI > 0$, there is an excess of AB (l) in the solution, and the solution is oversaturated. When $SI < 0$, the solution is undersaturated.

AB can be any species, and the stoichiometry can be more complex than in this simple example. The saturation point (or the equilibrium constant) depends on the temperature and pressure of solution and is different for each species.

When a solution is oversaturated, precipitation may occur. Nevertheless, kinetics also play a role: for homogeneous precipitation (in the absence of an external surface), an SI of 3–4 is to be applied in general, whereas for heterogeneous precipitation, an SI of 1–2 is needed.

Precipitation of a supersaturated solution is important for membrane applications in two ways. First, the increase of the concentration of rejected species in the retentate may lead to oversaturation, depending on the initial concentration and the ratio of permeate to feed. These

species, typically salts, can subsequently precipitate on the membrane surface and block permeation; this phenomenon is referred to as scaling. Scaling leads to an increase in energy consumption and chemical cleaning frequency. The most well-known sparingly soluble salts are CaSO_4 and CaCO_3 (Pervov 1991), but other salts may also precipitate, such as BaSO_4 and phosphate and silica salts (Semiati et al. 2003, Chesters 2009). Solutions to prevent scaling include the use of antiscalants or acids such as hydrochloric acid (HCl) and sulfuric acid (H_2SO_4). The use of acids is an effective solution, since the solubility of salts increases significantly at lower pH. Sulfuric acid is the most commonly used acid for this purpose.

Saturated and Supersaturated Solutions, Table 1 Pretreatment methods and their effect on scaling in reverse osmosis (Baker 2001) (XX highly effective, X moderately effective)

Saturated and Supersaturated Solutions, Fig. 1 High-purity NaCl salts obtained in a membrane crystallizer (Drioli et al. 2004, used with permission of Elsevier)

However, the trend is to use more hydrochloric acid, because sulfuric acid can negatively influence the fouling speed of a membrane by the addition of sulfate ions, which can stimulate precipitation of e.g., gypsum (CaSO_4).

A separate unit for removal of the scalant prior to the membrane separation might be necessary (Bremere et al. 1998), especially when going from high to very high feed recoveries (very high permeate to feed ratio). Some pretreatment methods and their effect on scaling are summarized in Table 1 (Baker 2001). However, a higher recovery shifts the problem to scaling of other salts with lower initial concentrations, which are not removed in advance. In any case, diagnosis, prediction, prevention, and control of scaling are important in any membrane application with scaling potential (Vrouwenvelder et al. 2003).

The membrane process in which the highest risk for scaling is encountered is reverse osmosis, because ions present in sparingly soluble salts are rejected by reverse osmosis membranes. Other processes related to salt removal or transport, such as electrodialysis and nanofiltration (and to a lesser extent, forward osmosis), are also at risk.

Supersaturation of salts is also crucial – and in this case a desired phenomenon – in the membrane crystallizers. It has been shown that in a membrane contactor producing supersaturated solutions, crystals with extremely high purity can be obtained, as shown in Fig. 1 for NaCl (Drioli et al. 2004). Similar results can be obtained for CaCO_3 and $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ as solid products. Crystal growth generally starts at solute concentrations at which the nucleation occurs; the growth rate, depending on the supersaturation degree, is determined by a combination of the nature of the growing crystal surface and the diffusional rate (Curcio et al. 2001). Direct contact membrane distillation can be employed to reach the supersaturation required for crystallization.

Antiscalant

Introduction

Antiscalants (scale inhibitors) are used in drinking water and process industry to prevent scaling or scale deposits on the membrane surface in a membrane-operated water treatment plant. Scaling occurs when the solubility limit of sparingly soluble salts/minerals is reached leading to the salt precipitation on the membrane surface as the temperatures and pressures change. Scale inhibitors delay this process and allow higher concentrations of salts resulting in enhanced water recovery. Antiscalants are stable in process equipment and are slowly biodegradable in the receiving surface water.

What Is Scale?

Scale is a white chalky buildup of calcium minerals that occur as a result of the precipitation of normally soluble solids that become insoluble as temperature increases. Common examples of scale are calcium carbonate (CaCO_3), calcium sulfate (CaSO_4), barium sulfate (BaSO_4), and strontium sulfate (SrSO_4). Equally problematic are silica (SiO_2) and calcium fluoride (CaF) scales. Over time, without proper treatment, scale and other contaminants build up and reduce the flow. RO scale inhibitors eliminate scale and reduce fouling on the membranes, while specific scale inhibitors reduce corrosion on the boilers. The scale inhibitors prevent undesirable scale buildup on the equipments and affect the efficiency. Appropriate treatment by scale inhibitor, conforming to the source water chemistry, will extend the life of industrial equipment and provide optimal process condition.

Process Description

The chemical treatment of water associated with oil and gas includes the application of scale inhibitors – phosphonates – to help maintain the integrity of equipment used during the drilling and production phases. Treatment is used to reduce the concentration of scale-forming compounds. The accumulation of scale can reduce flow rates or lower the efficiencies in heat exchanger. The inhibitors can be applied downhole of the well-head and classified as:

- Oil miscible
- Totally water-free
- Emulsified and solid

Technical Capabilities

Available scale-inhibiting chemicals are effective at preventing mineral deposits caused by compounds such as CaCO_3 , SrSO_4 , CaSO_4 , BaSO_4 , FeS , and FeO . Appropriate scale inhibitor and dose will identify types and concentrations of scale-forming compounds in the water. Phosphonate-based scale inhibitors are effective in preventing carbonate and sulfate scales, whereas polymer base inhibitors are effective for sulfate/carbonate scales of barium, strontium, and calcium.

Reverse Osmosis (RO)

RO is a pressure-driven process, while its pretreatment being site specific is dictated by the raw water chemistry. Antiscalants reduce the extent of contaminants that attach to the membrane surface during operation. Primarily, they delay or retard the process of membrane fouling. Many antiscalants combat scaling and fouling by bonding with the contaminants in the water, thereby preventing it from attaching or sticking to the membrane surface. These contaminants are finally directed to the RO reject or drain.

A variety of antiscalants are available with varying chemistries based on phosphonates, phosphates, acrylates, maleic and carboxylic acids, and dendrimers. Selection of antiscalant is site and application specific; they have different capabilities for inhibiting scales that are encountered in RO system. Different antiscalant chemistries have unique mechanisms for slowing crystal growth. However, the antiscalants delay crystal formation by slowing induction time – *the time between nucleation (birth of a new crystal) and crystal growth*.

Three methods of scale control employed are:

- Acidification
- Ion exchange (zeolite) softening
- Antiscalant addition

Acidification

Acid addition destroys carbonate ions, removing one of the reactants necessary for calcium

carbonate precipitation. This is very effective in preventing the precipitation of calcium carbonate while ineffective in preventing other types of scale. Disadvantages include corrosivity of the acid, the cost of tanks, monitoring equipment, and the fact that acid lowers the pH of the RO permeate.

Ion Exchange Softening

Sodium is utilized here which is exchanged for magnesium and calcium ions that are concentrated in the RO feed water:

(NaZ represents the sodium exchange resin)

When all the sodium ions have been replaced by calcium and magnesium, the resin is regenerated with brine. Ion exchange softening eliminates the need for continuous feed of either acid or antiscalant.

Threshold Inhibition

It is the ability of an antiscalant to keep supersaturated solutions of sparingly soluble salts. It prevents the precipitation of salts once the salt has exceeded its solubility product. The chemical inhibitors retard or delay the clustering process of charged ions and protonuclei. The most effective threshold inhibitors are based on phosphonic acids (or their salts) which have the added advantage of sequestering iron in a stoichiometric reaction. This is critical in membrane application as any soluble iron will cause rapid fouling while it oxidizes and becomes insoluble.

Performance

Antiscalant offers a variety of performance and application benefits. They are a powerful inhibitor tool against a variety of scales listed below.

CaCO ₃	CCPP >900 (LSI >2.8)
CaSO ₄	3.0 × K _{sp}
BaSO ₄	105 × K _{sp}
SrSO ₄	20 × K _{sp}
CaF	1,000 × K _{sp}
SiO ₂	120 ppm

The available antiscalants are highly effective at low dose rates in a wide range of feed water types and pH ranges. They provide both scale and inorganic fouling control while compatible with all membrane configuration and types.

Tricalcium phosphate	(Mg) (OH) ² /K _{sp} Mg(OH) ²

Material Safety Data Sheet (MSDS)

A Material Safety Data Sheet is a document that contains information on the potential hazards (health, fire, reactivity, and environmental) and how to work safely with the chemical product and an essential starting point for the development of a complete health and safety program. It also contains information on the use, storage, handling, and emergency procedures related to the hazards of the material. The MSDS contains much more information about the material than the label. MSDSs are prepared by the supplier or manufacturer of the material. It is intended to tell what the hazards of the product are, how to use the product safely, what to expect if the recommendations are not followed, what to do if accidents occur, how to recognize symptoms of overexposure, and what to do if such incidents occur.

The following categories of information must be present on the MSDS:

- Product information – product identifier (name), manufacturer and suppliers names, addresses, and emergency phone numbers
- Hazardous ingredients
- Physical data

- Fire or explosion hazard data
- Reactivity data: information on the chemical instability of a product and the substances it may react with
- Toxicological properties: health effects
- Preventive measures
- First aid measures
- Preparation information: who is responsible for preparation and date of preparing the MSDS

Scale Prediction and Saturation

Water is said to be saturated with a compound such as calcium carbonate if it will not precipitate the said compound or dissolve any of the solid phase of the compound when left undisturbed, under the same conditions, for an infinite period of time. Water that will not precipitate or dissolve a compound is at equilibrium for that compound.

The amount of a chemical compound that can be dissolved in water and remain in solution for this infinite period of time is described by the solubility product (K_{sp}). In the case of calcium carbonate, solubility product is defined by relationship:

$$(Ca)(CO_3) = K_{SP},$$

where (Ca) is the activity of sodium.

(CO_3) is the carbonate activity.

K_{SP} is the solubility product for calcium carbonate at the temperature.

In a more generalized sense, the term (Ca) (CO_3) can be called the ion activity product (IAP) and the equilibrium condition described by the relationship $IAP = K_{sp}$.

Scale indices developed are derived from the basic concept of saturation:

- If a water is undersaturated with a compound, $IAP < K_{sp}$. It will tend to dissolve the compound.
- If a water is supersaturated with a compound, $IAP > K_{sp}$. It tends to precipitate the compound.
- If a water is at equilibrium with a compound, $IAP = K_{sp}$. It tends not to dissolve or precipitate the compound.

Scale Inhibitor, Table 1 Antiscalant consumption

Consumption (kg/h) without second-pass brine recirculation	
First-pass RO	13.3
Second-pass front/rear	3.2/3.8
Total	20.3
Consumption with recirculation	
First pass	9.5
Second-pass front/rear	3.2/0.6
Total	13.3
Consumption in conventional RO design	
First pass	7.0
Second pass	7.0
Total	14.0

IAP = ion activity product; K_{sp} = solubility product.

Table 1 summarizes the overall results of antiscalant consumption at 300-ML/day of Adelaide (Southern Australia) Desalination Plant (ADP). It has been estimated that the antiscalant dose at this facility shall be 5 % lower than for a conventional RO design due to brine recirculation of the second pass ahead of the RO process.

Dosage Optimization

Induction time. Reactions do not occur instantaneously. A time delay occurs when all reactants are combined. They must come together in the reaction media to allow the reaction to occur. Thermodynamic evaluations of a water scale potential predict what will happen if water is allowed to sit undisturbed under the same conditions for an infinite period of time. Scale inhibitors do not prevent precipitation; they delay the inevitable by extending induction time (Ferguson 1984, Ferguson et al. 2011; Gill et al. 1983; Tomson et al. 2002; Amjad and Masler 1985).

Time selected is the residence time the inhibited water will be in the system. The inhibitor must prevent scale formation or growth until the water has passed through the system and been discharged.

Temperature affects the rate constant for the induction time relationship. As in any kinetic formula, the temperature has a great effect on reactants collision frequency. This effect is

independent of the effect of temperature on saturation-level calculations. A basic chemistry concept is that reaction rates increase with temperature. The rates approximately double for every 10 °C increase in temperature.

pH affects saturation level, but it also affects the dissociation state and stereochemistry of the inhibitors (Tomson et al. 2002). By virtue of its impact on the charge and shape of an inhibitor molecule, inhibitor effectiveness can be a function of *pH*, but may not always be significant in the *pH* range of interest (6.5–9.5). Acid dosage and consequently the *pH* of the medium have a significant bearing on the antiscalant dosage in a membrane-based treatment plant. Few BWRO (Brackish Water Reverse Osmosis) units can run without scale inhibitor.

Concentration Polarization

Concentration polarization is a phenomenon in which ion concentrations in a membrane's boundary layer are projected to be higher than those of the bulk water. The amount of boundary layer concentration can vary from 1.12 to 1.4 × that of the bulk water for clean membranes (Byrne 2002). Higher concentrations have been reported for fouled systems due to "cake-enhanced" concentration polarization.

Concentration polarization can affect all concentration-dependent calculations, including:

- *pH*
- Brine ion concentrations
- Recovery limits
- Maximum recovery based on antiscalant saturation-level maximum
- Dosage

Conclusion

Dosage models are available or can be developed for new inhibitors that allow accurate prediction of dosage requirements and treatment failure points. Specific scale inhibitors have been

developed for specific applications like for cooling systems, steam boiler systems, sulfamic acid-based descaler, corrosion nitrite inhibitor for chilled system, corrosion inhibitor (hard water) for open cooling systems, and air conditioning plant. Appropriate inhibitor is chosen after predicting the scaling tendency of the medium. Corrections in the modeling in high TDS brine are required as RO predictions lack accuracy due to use of simple indices. Such corrections are required for noncarbonate alkalinity and free ion concentrations. Scale inhibitor is an indispensable chemical in water and non-water segment. They aid in keeping the membranes from fouling so that the water will flow smoothly through. It is highlighted that appropriate selection or rather optimization of RO configuration can result in savings of up to 5 % as compared to conventional design.

Screen Printing of Membranes

Tauqir A. Sherazi

Department of Chemistry, COMSATS Institute of Information Technology, Abbottabad, Pakistan

Screen Printing

Screen printing is simple, economical, and versatile than traditional printing techniques. This technique is more suitable for flat or relatively flat surface; however, it could also work with less planar surfaces. A screen or fine mesh tightly stretched with a rigid frame is required. During printing, the undesired area of the mesh or screen is masked out according to the desired printing sketch. The screen is then positioned over the object to be printed and the ink is applied onto the screen followed by pressing the ink through the screen using squeegee. The distribution of masked and unmasked area of the screen design the print on the object followed by drying or curing. Proper postprint curing makes the print permanent and retains even under severe conditions. A variety of inks can be applied to a range of materials such as ceramics, textile, glass, metal, paper, and plastic. Consequently, screen printing is used in many industries including textile, medical devices, advertizing, snowboard graphics, decals, printed electronics, thick film technology, solar cells, fuel cells, membrane switches, etc.

Applications

Membrane Switches

Screen printing is commonly used in manufacturing process of membrane switches where circuit printing, graphic printing, and sometimes printing of industrial material such as adhesives and spacer layers can be achieved. Since membrane switches are used to enter function commands, they have wide range of applications in electronics such as

cellular phones, calculators, remote controls, machine controls, microwave ovens, and kitchen appliances, etc.

Screen printing offers a wide range of wet ink deposit thicknesses from which to create the circuits (from a few microns to several hundreds of microns). Moreover, printing of viscous conductive, resistive, and adhesive materials could be achieved. Inks used for membrane switches include polymer thick film silver conductive and resistive inks, adhesives, and solvent based (vacuum forming) and graphic UV-curing inks. Substrate materials typically used in membrane switch fabrication include polyester foils for the circuit layers and polycarbonate for the graphic overlays (Membrane Switches 2013).

Fuel Cell Membranes

Membrane electrode assembly (MEA) is an important part of fuel cells. Fabrication of MEA also involves the coating of catalyst layer onto membrane or to the gas diffusion layer. Catalyst layer structures can be modified by changing coating methods which significantly affect the performance of MEA. Spraying, screen printing, brushing, and decal methods have been applied to fabricate catalyst layers and carbon electrode layers to find out the economic ways suitable for mass production.

Spraying method and brushing method are widely used at laboratory scale but these methods are difficult to apply on large scale/mass production (Yoon et al. 2003). Sputtering is another interesting method for coating a small amount of catalyst in a vacuum, although it shows low single cell performance (Huang et al. 2006). The coating performed by decal method showed low electrochemical performance when applied to hydrocarbon polymer electrolyte membrane (PEM), which limits mass production and its application to various types of PEMs (Cho et al. 2009; Jeon et al. 2010). Owing to the advantages of reproducibility, easy procedures, and economic catalyst usage for mass production, the screen-printing method is proved as an efficient way to

coat the membranes with catalyst layer for fuel cells applications (Rajalakshmi and Dhathathreyan 2007).

Sensors

Sensors can also be fabricated by screen-printing technique. The chemical sensor consisting of transducer, sensitive membrane, and housing can be imagined as a system of layers. In such a planar potentiometric electrode, one layer can work as an electric contact of the electrode. The sensitive membrane can be the next layer, and finally the insulating layer that represents (together with the substrate) an equivalent of a conventional electrode body (Tymecki et al. 2006; Koncki et al. 1999).

Secondary Growth Method

► Seeded Hydrothermal Synthesis for Zeolite Preparation

Secondary Growth Method for Zeolite Membrane Preparation

Catia Algieri

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Self-standing zeolite membranes are brittle and thus they are synthesized on porous supports to confer to the membrane mechanical resistance. The methods principally used for the zeolite membrane preparation are one-step (Vroon et al. 1998) and secondary growth (Lovallo et al. 1998). In the first one, the support is immersed in a suitable hydrothermal system and the membrane is synthesized under autogenous pressure. In this case, the membranes present defects due to the lack of connectivity between the crystals. In the secondary growth, the nucleation is decoupled from the crystal growth and so with the possibility to optimize the conditions of each state, independently. It presents two steps: seeding and growth. During the first phase, zeolite nanocrystals, prepared previously, are deposited on the support surface. In the second step, the seeded support is put in contact with a solution that favors the crystal growth by hydrothermal treatment. This method is more reproducible than the one step and at the same time permits to prepare thinner layer. In this method the very critical step is the seeding. In fact, if the seeded layer is sufficient uniform, the membrane is almost defect-free. However, the achievement of this result is not a very trivial task. The seeding procedures reported in literature (Lovallo et al. 1998; Kusakabe et al. 1999; Huang et al. 2004) permit to prepare membranes with

better permeation properties than those prepared with the one-step method. However, they present drawbacks that do not allow to prepare membranes' defect-free. Two of the most used are dip coating and rubbing. The first one, owing to the negative action of the gravitational force, leads to the formation of layer too rough and not very uniform (Hasegawa et al. 2002). In the rubbing (Kusakabe et al. 1999) small brushes are used to implant seeds on the support surface. It is not reproducible and the layer is not regular. More controllable seeding procedures involve the filtration of a zeolite water slurry through a porous support (Huang et al. 2004; Pera Titus et al. 2005). The cross-flow mode is the best way for obtaining a very thin layer because the zeolite slurry is pumped tangentially along the support surface. Using tubular support the layer is not uniform due to the negative action of the gravitational force. This disadvantage is overcome by combining the support tilting and rotation with the cross-flow filtration (Algieri et al. 2009). The slow rotation allows a crystals deposition on the whole membrane area. The tilting ensures the removal of bubbles air formed during the filtration and responsible of local defects.

SEDE (Steric, Electric, and Dielectric Exclusion) Model: Approximated Versions

Patrick Fievet

Institut UTINAM, University of Franche-Comté, Besançon, France

DSP&DE Model: Approximated Versions

The DSP&DE model (known as the SEDE model in literature) is a transport model for nanofiltration (NF) which describes the separation properties as being the result of size effects, Donnan exclusion, and dielectric exclusion in terms of both Born dielectric effect and image forces contribution. The approximated versions of this model consider the dielectric exclusion (DE) in terms of only Born dielectric effect or only image forces.

DSP&DE (Image Forces) Model

Dielectric exclusion via image forces arises as a consequence of the difference between the dielectric constant of the membrane matrix (ϵ_m) and the dielectric constant of the solution in the nanopores (ϵ_p). Owing to the electrostatic effects resulting from the dielectric discontinuity, the ions in solution polarize the pore surface and interact with the polarization charges induced at the interface between the two dielectric media. The DE resulting from image forces has been extensively studied by Yaroshchuk (2000) who derived approximate expressions for the interaction energy in pores of cylindrical and slit-like geometries. These equations account for the screening of the interaction between the ion and the polarized interface by the membrane fixed charge and the ionic atmosphere as well.

The expression of the interaction energy $\Delta W_{i,im}^{int}$ (scaled on $k_B T$) for slit-like pores (which is mathematically less intense than that for cylindrical pores) takes the form:

$$\Delta W_{i,im}^{int} = -\alpha_i \ln \left[1 - \left(\frac{\varepsilon_p - \varepsilon_m}{\varepsilon_p + \varepsilon_m} \right) \exp(-2\mu^{int}) \right] \quad (1)$$

with

$$\alpha_i = \frac{(z_i F)^2}{8\pi\varepsilon_0\varepsilon_p R T N_A r_p} \quad (2)$$

and

$$\mu^{int} = \kappa r_p \sqrt{\frac{\bar{I}^{int}}{I^{int}}} \quad (3)$$

where z_i is the charge number of ion i , F is the Faraday constant, ε_0 is the vacuum permittivity, R is the ideal gas constant, T is the absolute temperature, N_A is the Avogadro number, r_p is the pore half-width, κ is the Debye parameter, and I is the ionic strength. The superscript int refers to a magnitude at the membrane/external solution interface and the bar to a magnitude inside the membrane. The parameter μ^{int} controls the screening of the interaction between the ion and the surface (via the image forces).

Some authors (Vezzani and Bandini 2002; Bandini and Vezzani 2003) assume that the role of the image forces is dominant as compared with the Born dielectric effect and neglect the variation of solvent dielectric properties in confined pores. ε_p in Eq. 1 is then replaced by the dielectric constant of the bulk solution (ε_b). This simplification is justified by the fact that the difference between ε_m and ε_b for most polymers is larger than the difference between ε_p and ε_b . In any case, the effects due to image forces are collected in the partition coefficients at the membrane/external solution interfaces, through energy terms ΔW_i .

As shown by Eqs. 1, 2, and 3:

- The transfer of an ion i from the external solution into a nanopore is unfavorable ($\Delta W_{i,im}^{int} > 0$) when $\varepsilon_p < \varepsilon_b$
- The magnitude of image forces is controlled by the square of the ion charge. Consequently, it does not differentiate (qualitatively) between co-ions and counterions (unlike the Donnan exclusion which repels co-ions but attracts counterions) and both co-ions and counterions are excluded from the membrane pores provided $\varepsilon_m < \varepsilon_p$.
- The magnitude of image forces decreases with increasing pore size. It should be noted that the magnitude of image forces strongly depends on the pore geometry, the dielectric exclusion in cylindrical pores being stronger than in slit-like ones (Yaroshchuk 2000)
- The screening of image forces is most relevant for concentrated solutions
- Unlike the Donnan effect, the Born dielectric effect exists even in the case of uncharged membranes.

DSP&DE (Born Effect) Model

Some authors (Bowen and Welfoot 2002a, b) consider that due to the small pore size of NF membranes, ε_p approaches ε_m , reducing the effect of image forces. Therefore, this phenomenon is ruled out from their model and the Born DE is considered dominant.

The Born dielectric effect is due to the lowering of the dielectric constant of the solution inside pores (ε_p), with respect to the corresponding value in the external bulk solution (ε_b), which is caused by an alteration of the solvent structure when it is confined in nanodimensional pores. Indeed, the equilibrium and dynamical properties of a solvent in a confined geometry-like pores of NF membranes can differ significantly from those in the bulk (i.e., outside pores) because solvent molecules in such environments exhibit a greater degree of spatial and orientational order. This ordered structure reduces the ability of the solvent molecules to respond to an external electric field and, hence, leads to a decrease in the solvent dielectric constant. The reduction of dielectric constant means there is an energy barrier to solvation of ions into the pores (resulting in an ion

SEDE (Steric, Electric, and Dielectric Exclusion) Model: Approximated Versions,

Fig. 1 Schematic cross-section view of a cylindrical pore with ordered single layer of solvent at the pore surface and an inner annulus having bulk physical properties

partition at the interfaces between the membrane and external solutions), which can be estimated on the basis of the Born model (Born 1920) as:

$$\Delta W_{i, \text{Born}}^{\text{int}} = \frac{(z_i e)^2}{8\pi\epsilon_0 k_B T r_i} \left(\frac{1}{\epsilon_p} - \frac{1}{\epsilon_b} \right) \quad (4)$$

where z_i is the charge number of ion i , r_i is its radius, e is the elementary charge, ϵ_0 is the vacuum permittivity, k_B is the Boltzmann constant, and T is the absolute temperature. The ion radius (r_i) used in the original Born model is the bare ion radius. However, it is well documented that the Born model overestimates solvation enthalpies, especially for cations (Israelachvili 1991). Therefore, other ion radii as the Stokes radius (Bowen and Welfoot 2002a, b; Déon et al. 2009; Oatley et al. 2012) or the cavity radius (Szymczyk and Fievet 2005; Bouranene et al. 2009) are usually used in Eq. 4.

As shown by Eq. 4:

- The transfer of an ion i from the external solution into a nanopore is unfavorable ($\Delta W_{i, \text{Born}}^{\text{int}} > 0$) for any ion irrespective of the ion polarity (provided $\epsilon_p < \epsilon_b$)
- Multivalent ions are more strongly rejected than monovalent ones (provided $\epsilon_p < \epsilon_b$)
- The interaction is stronger for small ions
- Unlike the image forces, the Born effect does not depend on geometry and pore size
- Unlike the Donnan effect, the Born dielectric effect exists even in the case of uncharged membranes.

It must be stressed that the calculation of the excess solvation energy requires knowledge of ϵ_p

and, unfortunately, there is no independent direct measure of this quantity at the present time. Therefore, ϵ_p is used in most current NF models as no more than a fitting parameter to describe the ion rejection rates (Bowen and Welfoot 2002a, b; Bowen et al. 2004; Déon et al. 2009; Cavaco Morão et al. 2008; Bouranene et al. 2009; Oatley et al. 2012).

However, some authors (Bowen and Welfoot 2002a; Oatley et al. 2012) proposed a model for describing the solvent structure within the pores, in which the solvent is assumed to be consisted of a single layer of oriented water molecules at the pore surface and an inner part having bulk dielectric properties (Fig. 1). The variation of average pore dielectric constant can then be calculated on a geometric basis as:

$$\epsilon_p = 80 - 2(80 - \epsilon^*) \left(\frac{d}{r_p} \right) + (80 - \epsilon^*) \left(\frac{d}{r_p} \right)^2 \quad (5)$$

where ϵ^* is the dielectric constant of the single layer of oriented water molecules, 80 is the ϵ_b value, and d is the diameter of a water molecule (0.28 nm).

As shown by Eq. 5, the reduction of the dielectric constant ϵ_p originates only from confinement and does not depend on local ion environment, i.e., on type and concentration of ions. Moreover, the dielectric properties of the oriented solvent layer (ϵ^*) are expected to be controlled by the solvent-membrane interaction. Therefore, a stronger interaction, resulting, e.g., from a more strongly charged membrane, could lead to increased orientation and association and thus reduce ϵ^* . If ϵ^* is influenced by the fixed charges

on the pores and/or the membrane material (hydrophilic/hydrophobic, organic/inorganic...), then this parameter also becomes a fitting parameter. To date, the single oriented solvent layer approximation has not been sufficiently investigated to validate it.

Seeded Hydrothermal Synthesis for Zeolite Preparation

Reyes Mallada

Department of Chemical and Environmental Engineering and Aragon Nanoscience Institute, Universidad de Zaragoza, Zaragoza, Spain

Synonyms

[Ex situ zeolite synthesis](#), [Secondary growth method](#)

The hydrothermal synthesis procedures used to prepare zeolite membranes can be classified in two general groups: *ex situ* and *in situ* methods, that is with and without a previous seeding step. The secondary (seeded) growth method, decoupling nucleation and membrane growth, is considered as the most successful approach to control membrane formation (Caro et al. 2000; Arruebo et al. 2008).

This method includes a first step, seeding step, in which a closely packed layer of colloidal zeolite crystals, synthesized homogeneously, is deposited onto the surface of a support. These seeds, act as nuclei for further crystal growth with a secondary gel under hydrothermal synthesis conditions in the second stage, see Fig. 1.

The coating or seeding methods for zeolite membranes are dip coating, slip casting, rubbing, spray coating, laser ablation, spin coating, vacuum seeding, using of electrostatic forces, and covalent linkage. The attachment and bonding properties of the crystals on support depend on the chemical potential of the support to interact or react with the approaching zeolite crystal or crystal growth front. Because the concentration needed for secondary growth is lower than that

Seeded Hydrothermal Synthesis for Zeolite Preparation, Fig. 1 Scheme of the hydrothermal synthesis of zeolite membranes by separating the nucleation and the crystal growth steps

Seeded Hydrothermal Synthesis for Zeolite Preparation, Fig. 2 SEM analysis of silicalite membranes over nonporous alumina substrates after 20 h of secondary growth synthesis conditions. *Left*: top view. *Right*: cross section

required for nucleation, further nucleation is strongly decreased and almost all of the crystal growth takes place over the existing crystal seeds. By controlling the composition and concentration of the secondary growth solution, the crystallization of undesired zeolite phases and the dissolution of the support can be avoided, and the rate

and direction of crystal growth can, to a certain extent, be controlled, see Fig. 2.

The aim of using the “ex situ” techniques is to obtain a better control of the microstructure and a preferential orientation of the crystals in the membrane with a shortened crystallization time. Preferential orientation is needed, not only for

Seeded Hydrothermal Synthesis for Zeolite Preparation,

Fig. 3 Schematic orientation of c-oriented MFI zeolite crystal

separation purposes when high fluxes are required, but also for size-selective chemical sensors. Due to the anisotropy in the pore geometry of the zeolite crystals, the orientation which shows the largest channels in the direction of the flux is preferable.

For example, on MFI zeolite, the straight and sinusoidal channels run parallel to the “b” and “c” axis respectively, see Fig. 3 Arruebo et al. 2008). The membranes prepared by secondary growth have rendered, in general, “c” oriented membranes, i.e., sinusoidal channels perpendicular to the support surface.

Seeding for Zeolite Membranes

Anne Julbe and Martin Drobek
Institut Européen des Membranes, Université de Montpellier, Montpellier, France

The seeding process can be described as a method in which a small piece of a single crystal/poly-crystal (seed) is used to act as an active site (nuclei) for growing a larger crystal when exposed to the effect of nutrients (liquids or gas) in a reaction system. The addition of seeds shifts the equilibrium toward crystal formation and avoids the undesirable random nature of spontaneous nucleation. This procedure is typically applied for solutions during recrystallization processes, thus eliminating the need for molecular collision/interaction and decreasing significantly the time required for nucleation. The seeding strategy is also largely applied for growing uniform zeolite membranes on porous supports, starting from a layer of closely packed seed crystals which have been previously nucleated (Julbe 2007). The decoupling of the nucleation step (at high supersaturation) from the crystal growth (at low supersaturation) makes the formation of a zeolite membrane very rapid as compared to direct growth without any seeds. As the concentration needed for secondary growth is lower than that for

Seeding

► Crystal Seeding

Seeding for Zeolite Membranes, Fig. 1 Layer of silicalite-1 (MFI) zeolite nanoseeds deposited by slip casting on a macroporous α - Al_2O_3 tubular support provided by Pall Exekia (Motuzas et al. 2006)

nucleation, further homogeneous nucleation is avoided and crystal growth occurs only on the existing seeds. Additional benefits include both the minimization or suppression of the crystallization of undesired phases and limitation of support dissolution (support etching might alter both its mechanical integrity and zeolite composition), while in some cases controlling the rate and direction of crystal growth. However, since the support is porous, uncontrolled infiltration of seeds in the pores might reduce membrane permeance by creating longer effective diffusion paths through the zeolite material (Hedlund et al. 2002). Controlled support seeding is therefore of great importance for growing uniform and good quality membranes, preferably with low infiltration into the porous support (Fig. 1). Classical coating or seeding methods are dip coating, slip casting, spin coating, rubbing, vacuum seeding, and spray coating. Specific methods for attaching zeolite seeds onto porous supports include either covalent linkage or electrostatic forces, using pH effects, cationic polymers, or silane coupling agents (Lai et al. 2004). Seeding with either commercial or homemade seeds is considered as one of the most attractive methods for preparing a variety of zeolite (e.g., LTA, MFI, SOD, FAU, CHA, DDR) and zeolite-type (e.g., MCM, MOF) membranes. It confers improved flexibility for controlling crystal growth and film

microstructure with high reproducibility and scalability. In industry, the seeding process is typically applied by Mitsui Engineering and Shipbuilding Co. Ltd. for the preparation of zeolite membranes, including LTA (Morigami et al. 2001).

Segmented Block Copolymer

Anja Car

Department of Chemistry, University of Basel,
Basel, Switzerland

Segmented block copolymers or multi-block copolymers with general formula $(AB)_n$ are linear macromolecules containing different rigid and flexible polymeric segment or block (Richard 2000). Usually, the flexible block has a glass transition temperature (T_g) below room temperature, whereas the rigid block has a glass transition temperature or melting temperature (T_m) distinctly higher (Holden et al. 2004). Microphase separation in the solid state derived from incompatible blocks is one of the most typical characteristic properties of segmented block copolymers (van der Schuur and Gaymans 2007).

The morphology depends on chemical compositions, chain structure, molecular weight of constituent blocks, thermodynamic interaction parameters, and used solvent during its process (Timothy 2003). They allow to extent significantly the property profiles of defined polymer materials by combining useful properties of two or more different prepolymers or polymers in one final product (Khastgir and Bhowmick 1998). The influence of the chemical structure and the chain length of segments upon the formation of “micro-domains” of the certain phase is very important and determines the final properties of polymer. Hence, at room temperature, these materials behave like elastomers, but at a temperature above T_g or T_m of the rigid block, the materials can be processed like thermoplastics (Richard 2000). Thus, these copolymers are considered as thermoplastic elastomeric materials, with several aspects of rubberlike behavior. Multi-block copolymers can be synthesized from different polymer segments having active functional groups at the chain end (Ebeling and Vana 2011). Basically, segmented block copolymers are formed in such a way that the chemical reaction employs both monomer and preformed functional terminated oligomers. Earlier, the segmented systems were synthesized through basic linkages involving isocyanate chemistry (Riegel and Kent 2003). In contrast to the segmented urethanes, amides, or urea copolymers, segmented polyester ether copolymers are generally prepared by the melt transesterification (Thomas et al. 2011).

Self-Bundling Electrospinning Method

Hongyang Ma, Benjamin S. Hsiao and Benjamin Chu

Department of Chemistry, Stony Brook University, Stony Brook, NY, USA

Self-bundling electrospinning is a technique used to induce alignment and self-bundling of electrospun nanofibers in the electrospinning process (Wang et al. 2008a). A typical electrospinning setup is employed in the self-bundling process, except that a grounded electrode (in the form of a needle tip which is used to induce the self-bundling of polymer nanofibers at the beginning of the electrospinning process) is inserted between the spinneret and the collection drum to alter the equal potential electric field lines between the spinneret and the collector. As a result, the shape of the equal electrostatic potential field lines has been changed. Then, the charged jet stream from the spinneret will be focused toward the tip of the inserted needle, promoting bundling of the formed electrospun fibers. The converged fibrous bundles could be wound around the drum to form a continuous self-bundling yarn. Empirically, the self-bundling has occurred when the conductivity of the polymer solution was higher than 10 $\mu\text{S}/\text{cm}$. Higher conductivity of the polymer solution than 400 $\mu\text{S}/\text{cm}$ could induce the self-bundling process simultaneously without using the grounded needle tip (Wang et al. 2008b). Moreover, by changing other parameters such as applied voltage, velocity of collection, solvent, polymer concentration, temperature, and humidity in the electrospinning process, the obtained electrospun nanofibers showed complex bundling structures.

Self-Bundling Electrospinning Method, Fig. 1 Representative electrospun nanofiber scaffolds with (a) typical and (b) self-bundling electrospinning methods (Wang et al. 2008a, b)

Self-bundled electrospun nanofibrous membrane exhibits unique mechanical properties as expected due to the aligned and bundled structure of the nanofibers and may be potentially useful in a variety of electrical, optical, mechanical, and biomedical applications. It should be noted that the production rate of the self-bundled nanofibers is relatively low at present; however, with the rapid development of multiple-jet electrospinning technology, this obstacle may be overcome (Fig. 1).

Separation and Recovery of Gases, Multistage Process for

May-Britt Hägg

Department of Chemical Engineering, Norwegian University of Science and Technology, Trondheim, Norway

Efficient separation of gases using membranes is dependent on several factors: The partial pressure of the gas to be recovered in the feed, the available

delta partial pressure over the membrane (feed - permeate), i.e., the driving force, the energy consumption needed for providing compression and/or vacuum, the purity demands for the product, and the value of the gas to be recovered. Typically increased driving force means increased flux and reduced membrane area, but at the same time increased energy consumption, hence there will be a trade-off between energy costs and capital costs. The type of flow patterns and flow velocities will also influence the efficiency of the separation – this has been nicely explained in the book of Geankoplis (2003).

Today the typical gas separation membrane process applications are hydrogen recovery from various types of gas streams (H_2 from synthesis gas, H_2 from refinery stream), oxygen–nitrogen separation for production of high purity N_2 - or O_2 -enriched air, CO_2 removal from natural gas (NG “sweetening”), upgrading of biogas (CO_2 - CH_4 separation), vapor gas separation (VOC recovery at oil terminals), and dehydration of air. The type of membrane materials used for the commercial processes today are relatively few, and they are polymers (cellulose acetates, polyimides, siloxanes). A dramatic increase in both new materials and applications is predicted (Baker 2012).

The separation taking place with the current polymer membranes is based on the solution-diffusion mechanism, and thus the difference in diffusion and solubility of the various gases in the membrane according to Eq. 1 expressing the flux of A through the membrane (J_A). In a gas mixture

the gases will be more or less nonideal, and the deviations from ideality are often more important than the difference in molecular size for the separation. Some of the new materials under development are using “carriers”; either fixed or mobile – this may add complexity to the process design, as the transport mechanism is now adding a second term to be considered (Eq. 2). Then finally, in precombustion separation of H_2 from CO_2 could possibly be performed using a palladium (Pd) membrane, by transporting H_2 as a proton (H^+) through the membrane; then the transport will basically follow Sieverts’ law (not discussed here):

$$J_A = \frac{P_A}{l} (p_h x_A - p_l y_A) \quad (1)$$

Separation and Recovery of Gases, Multistage Process for, Fig. 1 Recovery of volatile organic compounds (VOC) from air stream. Typically one-stage, highly permeable rubbery polymer (siloxane), but concentration in feed is usually low; hence, the concentration in the permeate will also be quite low even when 90 % have been removed (Baker 2012)

where P = permeability, l = thickness of membrane, Δp = driving force (in parenthesis)

$$J_A = \frac{P_A}{l} (p_h x_A - p_l y_A) + \frac{D_{AC}}{l} (c_{AC,0} - c_{AC,l}) \quad (2)$$

where the transport of the complexed compound AC is now added, D = diffusion coefficient, c = concentration.

All these considerations mentioned above must be taken into account when the membrane separation process is being designed, and various types of multistage processes can be optimized for the most efficient and economical separation. Quite often a recycle of retentate or permeate streams is needed or uses of sweep gas on permeate side to increase the driving force over the membrane. It is quite complex to design the preferred separation process, and simulations are needed – it is therefore not only one solution. Several good examples are illustrated in the books of Baker (2012) and Mulder (1996) and likewise in publications of Favre (2007) and Hussain and Hägg (2009).

Several scenarios can be pictured depending on gases to be separated. Some examples are given (Figs. 1, 2, 3 and 4).

Separation and Recovery of Gases, Multistage Process for, Fig. 2 Upgrading of biogas, typically two stages with recycle for minimizing the CH_4 -loss and produce high purity CH_4 – in this case four designs were

compared, in the process shown, 99 % of the CH_4 were recovered from a water saturated biogas containing 65 % CH_4 and 35 % CO_2 (Deng and Hägg 2010)

Separation and Recovery of Gases, Multistage Process for, Fig. 3 Recovery of CO₂ from flue gas – large volume gas streams; combination of low feed pressure and vacuum on permeate side may be most

economical – illustrated for a facilitated transport membrane with 10 % CO₂ in flue gas (Hussain and Hägg 2010) with 90 % CO₂ capture and 90 % purity

Separation and Recovery of Gases, Multistage Process for, Fig. 4 Last but not least; smart process solutions – here for CO₂ capture from flue gas using a

high-flux, moderate selective membrane, and using air as sweep on the second stage which is then fed to the boiler (MTR-process) (Merkel et al. 2010)

Separation of Organic from Organic Components (Pervaporation Application)

Alberto Figoli

Institute on Membrane Technology, National Research Council of Italy, ITM-CNR, Rende, Italy

Separation of organic-organic compounds is one of main areas in which pervaporation (PV) is employed together with solvent dehydration and removal of volatile organic compounds (VOCs) from aqueous solutions. Many organic compounds either have a close boiling point or they form azeotropic mixtures that cannot be efficiently separated by common techniques such as distillation. In this framework, pervaporation can be used to separate these mixtures alone or, most of the times, combined with distillation in a hybrid process in order to improve the separation efficiency.

Pervaporative organic-organic separation is the least developed field of application of pervaporation, and it is still very challenging principally due to the lack of membranes able to resist to the harsh conditions of solvents and the high temperatures required by the process (Baker 2004). In order to overcome the swelling effect and the degradation phenomenon caused by organic solvents, cross-linked membranes and blended polymeric materials have been developed and employed. On the other hand, inorganic and inorganic-polymer hybrid membranes gained a great acceptance, thanks to their high mechanical, thermal, and chemical stability.

The choice of using hydrophilic or hydrophobic membranes is based on the solubility of the target organic compound in a particular material.

With the installation of the first plant for the separation of methanol/methyl tert-butyl ether mixture in 1991, the commercial interest in the separation of organic mixtures through pervaporation started to rise. Over the last 50 years, organic pervaporation has been extensively investigated by the chemical and

petrochemical industries in which refinery streams contain a large number of organic components such as benzene, styrene, and toluene.

Pervaporative organic-organic separations can be classified as:

- (i) Separation of polar/nonpolar solvent mixtures such as methanol/methyl tert-butyl ether and ethanol/ethyl tert-butyl ether
- (ii) Separation of aromatic/aliphatic and aromatic/alicyclic mixtures such as benzene/cyclohexane
- (iii) Separation of aliphatic hydrocarbons such as toluene/isooctane
- (iv) Separation of isomers such as *m*-/*p*-xylene and *n*-/*t*-butanol (Smitha et al. 2004)

Sequential Dilution Diafiltration

Greg Foley

School of Biotechnology, Dublin City University, Dublin, Ireland

Sequential dilution diafiltration is simply another name for discontinuous diafiltration by sequential dilution.

It involves repeated dilution of a solution followed by batch ultrafiltration. In the dilution step, both the macrosolute product and the microsolute impurity are reduced in concentration.

In the subsequent ultrafiltration step, in which the ► **retentate** volume is reduced to its original value, the macrosolute, which is assumed to have a rejection coefficient of 1.0, is increased in concentration to its original value, while the

concentration of microsolutes, whose rejection coefficient is zero, remains at its value *post*-dilution.

Sequential dilution diafiltration can be performed as a multistage process, leading to a reduction in buffer consumption for a given reduction in microsolutes concentration.

Serum Proteins

Karin Schroen

Wageningen, The Netherlands

Roughly 10 kg of milk consisting of 4 % fat, 2.6 % casein, and 0.7 % serum protein, but mostly of water (Walstra et al. 1999), is needed to produce 1 kg of cheese. The fat and casein are mainly incorporated in the cheese, while the serum proteins together with κ -casein and most of the water become the whey. As indicated in Table 1, the whey proteins are considerably smaller (3–6 nm) than the casein micelles which are typically 20–300 nm.

Serum protein was previously considered a by-product, but nowadays, serum proteins have considerable economic value due to their outstanding emulsification, gelling, and foaming

properties, either as a serum protein isolate or concentrate or as a specific protein. To preserve these special properties, in some cases the cheese process is started from a concentrated casein stream, while most of the serum proteins are separated and don't receive a heat treatment that can be detrimental to their functional properties. We discuss here separation of serum proteins from regular serum, separation of serum protein from casein during a casein concentration step, and isolation of specific proteins.

The salt concentration in serum is high, and therefore demineralization is needed. Nanofiltration has a great benefit over ion exchange and electrodialysis that it reduces energy consumption and the partly demineralized can be processed further into powders (van der Horst et al. 1995). When comparing various membranes (PSF/PVP, ZrO₂, ZrO₂/PSF), Doyen and coworkers (1996) concluded that the flux of the membranes is determined by the fouling layer and not the permeability of the membranes. Prevention of gel layer formation is a critical step and limits the concentration factors that can be reached.
